were examined. Briefly it may be stated he found that if a spectrum was allowed to fall on a sensitised daguerrotype plate, which had received a preliminary exposure to white light, a remarkable phenomenon took place—a phenomenon which was also observable if weak white light were allowed to fall on the plate during its exposure to the solar spectrum. In developing such an image with mercury vapour, the blue, or most refrangible end of the spectrum was impressed in the usual way, that is to say, the Fraunhofer lines showed as dark lines on a lighter back-ground; at the red or least refrangible end of the spectrum, however, the Fraunhofer lines were seen as light on a darker back-ground; in other words, the photographic action was reversed, the neutral point of no action lying somewhere in the yellow. On studying a picture taken by this means, it was observed that in all cases the darkest Fraunhofer lines had the same tint, and that effect of light lines upon dark background, or dark lines upon the light background, were caused by alteration in tint of the background itself. Could this effect have anything to do with the oxidation? if it had it would indicate that the rays in the least refrangible end of the spectrum must *accelerate oxidation;* for it must be remembered that the plates had received an exposure to white light, either before, or during, exposure to the spectrum, and that the red rays prevented the development of the effect of the white light.

Now Draper had failed to get the same result on films of collodion containing the sensitive silver compounds, though he had obtained the reversal of the least refrangible end of the spectrum on such plates. If the theory

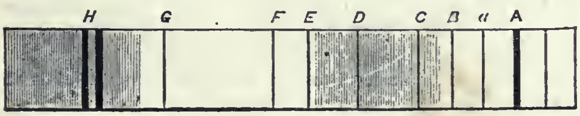

FIG. 3.

FIG. 4.

of oxidation held good for daguerrotype plates it ought also to hold good for the collodion films, and experiment decided once again in favour of the theory. Collodion films, which held *in situ* the blue form of silver bromide already alluded to, and which had been proved to be sensitive to the red end of the spectrum in the ordinary sense of the word (*i.e.*, that a proper negative picture of it could be obtained as it could of the blue end), were the subjects of experiment. It is evident, if the red rays were accelerators of oxidation, that in order to get a positive picture of the red end (*i.e.*, one answering to the reversal of the Fraunhofer lines in Draper's daguerrotype plates) the films should be exposed to the spectrum whilst in some oxidising medium, weak enough by itself, not totally to obliterate during the time of exposure to the spectrum any preliminary exposure which should be given to them, and yet strong enough to do so and to destroy the reducing action of the red rays, if these latter possessed a power of accelerating oxidation. Ozone, hydroxyl, nitric acid, and other oxidising agents, completely corroborated the idea that all the red rays had the power of accelerating oxidation, as the positive pictures of the red end here obtained, and in some case of the blue end, with negative pictures of the yellow and ultra-violet. The strength of the oxidising solutions was very small; thus, when nitric acid was used, four drops to a couple of ounces of water was found sufficient to cause this remarkable action to take place, whilst if the nitric acid were reduced in quantity, or omitted altogether, the effect of the ordinary negative picture was obtained in that part of the spectrum (Figs. 3 and 4). On the other hand, when the strength was increased, the image disappeared altogether. Figs. 3 and 4 show the results indicated above; the shaded portions show where the spectrum was photographed in the usual way, the white portions indicate where the reversed action took place.

We are not sure but we believe that Draper used silver iodide as his sensitive salt in the experiments with collodion, in which he failed to obtain these phenomena. The iodide is insensitive to the red end of the spectrum under ordinary conditions of exposure, being usually exposed in the presence of a solution of silver nitrate which clings to it after taking it out of the bath. It was found, however, if this free silver nitrate were washed away and if the exposure to the spectrum took place in the oxidising medium, after a preliminary exposure to white light, that this reversing action, as it is called, of the red end of the spectrum was obtained; and under certain conditions if the silver nitrate were removed, that the same results could be obtained even when the plate was not exposed in this oxidising medium.

Now regarding the reversal in the blue indicated above how can it be accounted for? By the very same theory, only an abandonment of the hypothesis that the least refrangible end of the spectrum *alone* is an accelerator of oxidation becomes necessary. In all comparative experiments made with the daguerreotype plate and the collodion film the difference of these conditions must be remembered. In the former the halogen liberated by the action of the light on the iodide combines immediately with the metallic plate forming fresh sensitive compound; in the latter the thickness of the sensitive compound has a limit, and much of it is altogether inoperative, the outside of the particles alone being available for the reducing action of light, and the halogen has to escape or be absorbed as best it may. In a collodion film it is manifest that the reduction of all the sensitive compound available must take place after a time, and when this is the case, if the same rays which effect reduction likewise accelerate oxidation, that the latter effect of the rays will have unimpeded action. So much for the theory, does experiment prove or disprove it? It is evident if the hypothesis be correct, that a film which is exposed to the action of light in a medium free from oxygen, or in one which is an absorbent of oxygen, should be incapable, on development, of showing this reversal of the ordinary action of light.

The results again showed that the theory was borne out, for it was found impossible to obtain a reversal of the image when so exposed. Here, then, we have a probable explanation of the phenomenon known as solarisation, to which allusion has already been made; it seems to be an oxidation of the undeveloped image.

W. DE WIVELESLIE ABNEY

(*To be continued.*)

NOTES

DR. O. FINSCH has resigned his appointment as Custos of the Museum of Bremen, and, as soon as the publication of his work on the results of the German Siberian Expedition of 1877 is completed, will leave Europe on a scientific mission to the Pacific and Australia. Dr. Ludwig, late Assistant in the Zoological Museum of Göttingen, has been appointed Dr. Finsch's successor.

WE notice the death at Cuenca, in Ecuador, on June 20, of Gustav Wallis, the botanist. He was born at Luneberg, in Detmold, May 1, 1830. In 1860 he was commissioned by the Lindens, the great horticulturists of Brussels, to gather new varieties of plants in South America, and during eight years, almost without cessation, he traversed Brazil, Peru, Ecuador,

Bolivia, Columbia, Panama, and Costa Rica, making everywhere enormous botanical collections. A similar journey to the Philippine Islands under the auspices of Veitch and Co., of London, followed in 1868, but in 1871 he was back again in his favourite field, the north-western portion of South America. Here he met his death in a hospital, reduced to poverty, and fairly worn out in the cause of science. Wallis stood fairly first among the travelling botanists of our day, possessing a rare combination of courage, energy, and scientific training. Not only were his contributions to botany of great value, but he actually introduced into European horticulture no less than 1,000 new varieties from across the ocean, and no small portion of the brilliant treasures of our modern conservatories are due to his unwearied zeal.

THE American Association met, under the presidency of Prof. O. C. Marsh, at St. Louis on August 21 and following days, and, judging from the reports that have reached us, the attendance was not quite up to the average, St. Louis having a bad reputation on account of its heat, this year aggravated by the dread lest the yellow fever might extend up the Mississippi Valley to the meeting-place of the Association. Vice-president Thurston gave the introductory address "On the Philosophic Method of the Advancement of Science," in which he traced the history of scientific research from early times, and advocated the establishment of a systematic method for discovering competent scientific writers, and endowing them adequately for the pursuit of research. Mr. A. R. Grote gave an address entitled "Education, a Succession of Experiences." Mr. Edison was present at the meeting for a short time and met with an enthusiastic reception; he read a paper on some of his inventions. A committee was appointed to arrange for a eulogy on the late Prof. Henry. We see from the neatly got-up *Daily Programme* of the Association that upwards of 100 papers were down to be read. We hope to give an account of the principal papers in an early number. The Association meets next year at Saratoga, on the last Wednesday of August, Mr. G. F. Barker of Philadelphia, president.

AT the recent International Congress of Anthropology several interesting reports were read by specially appointed reporters. M. Thulié gave a report on anthropological societies and education in anthropology. In tracing the history of anthropological societies in France and England, he showed the gradual progress which had been made in the objects and method of the science. M. Topinard's report was on astronomical, biographical, and pathological anatomy. He divided anthropology into general and special—the former embracing the human group as a whole and in its relation with the lower animals, the latter department being entitled "Zoological Anthropology;" special anthropology or ethnology investigates natural divisions, primitive or secondary, called *races*. Another division was into anatomical, biological, and pathological anthropology. Ethnographical reports were given by M. Girard de Rialle on Europe, Central and Western Asia, and America, and by M. Bordier on Africa, Eastern Asia, and Oceania. M. de Rialle called attention to the magnificent museums in the northern European countries, Sweden, Finland, and Russia, as contrasted with France, and still more markedly, we might say, with England. These reports were illustrated by reference to the fine collections shown at the Paris Exhibition. There were two reports in the department of prehistoric archæology, one by M. de Mortillet on geological times, and the other by M. Cartailhac on the neolithic period. In the report on demography (a sort of statistical anthropology), by M. Chervin, he gave a beautiful example of a statistical study by Dr. Berg, of the Swedish Statistical Bureau, who traces the influences of the Swedish wars between 1795 and 1810, generation after generation down almost to the present day. Dr. Lebon read an instructive paper on the results of his experimental researches on the variation of volume of the cranium in their relations to intelligence. He showed that intelligence was proportionate to the volume of the cranium, and that among the higher races the difference between the size of individual crania is less than among inferior races. A curious result is that among the women of the inferior races the cranium is generally larger than among those of the superior races; this result he ascribes to the insignificant part allotted to females in the active work of civilised society.

AMONG the resolutions passed by the International Congress on weights, measures, and coins, at Paris, was the following:—"The Congress learns with pleasure the progress of the metric system; it deplores that England, Russia, and the United States have not yet entered into the same path; and it is of opinion that the Governments of those countries should be solicited to give effect as early as possible to an act of progress so eminently useful to science, commerce, and international relations." The British and American members had a separate meeting, and resolved to petition their respective Governments to appoint a mixed Commission to consider the adoption of the metric system by both countries, and to make all necessary recommendations for the proper legislation to secure the desired end.

THE *Gazetta d'Italia* recounts a somewhat remarkable change in the surface of the earth at the village of Ortagli, a short distance south-east of Florence. In the course of a few days the tract on which the village stands has gradually sunk, until the depression amounts to about fifteen feet. It has not been sufficiently regular to prevent the houses from making threatening divergences from the perpendicular, and the population has taken refuge in the field. Strange to say another tract of land about two hundred yards from the village is, on the contrary, gradually rising, at times nearly rapid enough to be noticed with the eye. Several Italian *savants* are on the ground studying the strange phenomenon.

AT the next meeting of Russian Naturalists at St. Petersburg the question of chronology is again to be ventilated, with a view of proposing to the Government the change of date from the old style, now in use in Russia, to the new style used everywhere else in Europe and abroad.

ADMIRAL MOUCHEZ appointed two days every month when the Paris Observatory might be visited by the public, but the number of requests increase so much that he has been obliged to establish supplementary visits. On Saturday, September 7, the number of visitors exceeded a thousand. Admiral Mouchez intends giving a great *soirée* at the Observatory, on which occasion all the celestial objects drawn from nature by a clever artist will be shown with a magic lantern. He has asked from the Ministry of Public Instruction the loan of a portrait of Louis XIV., the founder of the Observatory. This portrait will be placed in the large saloon and surrounded by the portraits of Lalande, Laplace, Arago, Leverrier, and other great astronomers whose names have been associated with the establishment.

A COMMISSION was some time since appointed to report on the great reflector which Leverrier discovered to be imperfectly polished. The Commission has examined the instrument carefully, but unfortunately drawn up an ambiguous report, so that Admiral Mouchez is said to be left in a most perplexing position. The report does not say clearly that the instrument is good, but at the same time it gives no authority to reject it and to have it polished again. The perplexity is enlarged by the ineertitude on the results of works in course of execution. The polishing of the glasses of the large refractor has been placed in the same hands in pursuance of a contract signed by Leverrier long ago. It is expected that at the next meeting the Council of the

Observatory will give to the director the means of protecting efficiently the interests of Government and science.

MOUNT VESUVIUS is showing visible signs of agitation. An overflow of lava is considered probable on the side towards the Observatory.

AT a meeting of the Sunday Society a report was read from Mr. W. E. A. Axon, hon. secretary of the Manchester and Salford branch, announcing that, after a debate which had extended over three meetings, the City Council had, by a majority of 28 against 20, acceded to the memorial from the Sunday Society, and decided to open the several free libraries of the City on Sunday afternoons. Much satisfaction was expressed with Mr. Axon's report, and on the motion of Mr. Mark H. Judge, seconded by Mr. Frederick Long, a resolution was unanimously passed thanking the branch for the energy they have exhibited, and congratulating them upon the success they have achieved. The libraries were opened last Sunday for the first time.

ONE of the large monkeys at the Alexandra Palace had been for some time suffering from the decay of the right lower canine, and an abscess, forming a large protuberance on the jaw, had resulted. The pain seemed so great it was decided to consult a dentist as to what should be done, and, as the poor creature was at times very savage, it was thought that, if the tooth had to be extracted, the gas should be used, for the safety of the operator. Preparations were made accordingly, but the behaviour of the monkey was quite a surprise to all who were concerned. He showed great fight on being taken out of his cage, and not only struggled against being put into a sack prepared, with a hole cut for his head, but forced one of his hands out, and snapped and screamed, and gave promise of being very troublesome. Directly, however, Mr. Lewin Mosely, who had undertaken the operation, managed to get his hand on the abscess and gave relief, the monkey's demeanour changed entirely. He laid his head down quietly for examination, and, without the use of the gas, submitted to the removal of a stump and a tooth as quietly as possible.

THE *Daily News* Roman correspondent writes that from his villegiatura at Rocca di Papa, the archæologist Prof. Michael Stephen de Rossi, sends to the *Voce della Verità* an account of the earthquake that occurred there on the 3rd inst. At 11.13 P.M. of that day the inhabitants of the village were aroused by the very distinct shock of an earthquake, which was at first jerking, then undulatory in its movement, in a north-west south-east direction. The jerking lasted three seconds, but the undulatory stage occupied a considerable interval of time. In the seismographs the jerking stage of the phenomena was very strongly registered. What merits attention is that this shock coincided with a rise of the barometer,—at the close, that is to say, of an atmospheric storm. It happened when the temperature had barely reached its maximum for the season, thereby coinciding with the phenomena that took place on August 24 of last year. This earthquake was not unforeseen, although it was the first very perceptible one of which they have had experience this season. Already from August 24 there happened slight shocks, and sometimes they were felt even in Rocca di Papa. The instruments, particularly the tronometer, were continually agitated. On September 3 between 11.30 A.M. and 12.30 P.M., Prof. de Rossi counted eleven slight shocks, the most perceptible of them being that which occurred at 12.10 P.M. It was jerking on the 4th, the instruments being agitated in the most extraordinary manner, principally at 11.40 A.M. and between 2 and 5 P.M., at which time he also noticed two very tiny shocks. In the interval between August 24 and September 6 there were also felt some subterranean murmurs, for the study of which Prof. de Rossi did not, he regrets to say, put the microphone in operation. This wonderful instrument was scarcely dreamt of when he published his opinion that it could be applied to the observation of even the microphonic sounds which may accompany not only earthquakes but also microseismic movements. In fact, Count G. Mocenico, of Vicenza, tried for the first time to apply it for this purpose, with the result of hearing the most mysterious sounds which are produced under our feet in the depths of the earth. Prof. de Rossi ventures on no speculation as to the continuance and close of the actual seismic period. It is certain, however, he states, that it is found in strict relation with the extraordinary drought, of which, perhaps, as in the past year, it is the result.

WE have received a neat and well-illustrated guide-book to the new aquarium which has been opened in Princes Street, Edinburgh, under the direction of Dr. Andrew Wilson. The institution is intended to be utilised for instruction as well as for amusement, and in winter it is Dr. Wilson's intention to deliver occasional lectures of a popular kind adapted especially for school-children, who will thus, it is hoped, be incited to study natural history practically, or at least to take some interest in their living surroundings. When the arrangements are thoroughly completed it is hoped that a naturalist's table and small laboratory may be instituted. The directors, we are informed, appear to encourage as far as possible the educational features of the institution. We trust the institution will prove a success, and turn out an important addition to the educational resources of Edinburgh.

WE understand that Messrs. Chatto and Windus have in the press a volume of Essays and Lectures on Biological Subjects, by Dr. Andrew Wilson, of the Edinburgh Medical School. The work, under the title of "Leisure Time Studies," will be fully illustrated; some of the more prominent essays dealing with the relations of science teaching to ordinary education.

MR. W. S. SONNENSCHEIN will publish this year an English translation of Naegeli and Schwendener's well-known work, "Das Mikroskop. Theorie und Anwendung desselben," made by Mr. Frank Crisp, LL.B., B.A., Hon. Sec. to the Microscopic Society, and the publisher himself. The translation will be made from the last German edition, and will be supervised in part by Prof. Schwendener himself. The last chapter of the original (on Morphology) will be omitted, as having no reference to the microscope.

A GENEVA correspondent sends us a photograph showing the effects of lightning on an aspen (*Populus tremula*), situated in a wood near the Château of Crans on the shore of the Lake of Geneva. It was struck on August 9 last, in circumstances confirmatory of the views of Prof. Colladon (NATURE, vol. xvi. p. 568). The lightning chooses by preference the poplar as a conductor to reach the ground, and the case is striking here, where the tree is surrounded by other kinds, particularly firs, taller than it. Two great branches, of forty-five and fifty centimetres in diameter, which surmounted it, were struck by the lightning, and led it to the ground without having received the least apparent injury, while the trunk below them is absolutely shattered. This is a fresh proof that the upper part of trees, especially of poplars, is an excellent conductor of electricity, which only rends or shatters the wood when it finds a passage in the trunk. Other recent observations prove the preference of lightning for trees situated near streams or reservoirs of water, so that the best conductor for a house is a lofty tree, a poplar especially, situated between the house and a well, a pond, or a neighbouring stream.

AN interesting establishment was opened in the Champ de Mars, Paris, close to the École Militaire (within the precincts

of the Exhibition), a few weeks ago, and deserves notice. It is a technical library for French authors which now numbers more than 3,000 volumes. This library will be made permanent, and established somewhere in Paris when the Exhibition is over. It was originated by M. Tresca, the sub-director of the Conservatoire des Arts et Métiers.

THE weather being magnificent in Paris, the Giffard captive balloon takes up daily 500 passengers, paying twenty francs each, exclusive of a large number of *invités*, two aeronauts, and meteorological observers. M. Giffard has received propositions from the New York *Daily Graphic* for the purchase of his balloon, but he has declined; it will probably become a permanent institution in Paris.

THE Russian Technical Society at St. Petersburg has commenced the publication of polyglot technical dictionaries. The French-Russian-German-English part has just appeared.

THE rage for exhibitions has now spread even to Central Asia. The latest news from Tashkent states than an agricultural and industrial exhibition is about to be held there. Great preparations are being made for it at Samarcand, and the Government has promised gold and silver medals to the exhibitors as well as —honorary Kaftans!

WE recommend to all who have anything to do with the management of schools, two lectures by Dr. Liebreich, which have been published by Messrs. Churchill under the title of "School Life in its Influence on Sight and Figure."

THE botanist Fournier finds in Mexico 638 varieties of grasses, of which 376 occur in no other land. Of the remainder 82 are found in the United States, 30 on this side of the Atlantic, and the rest in the West Indies, South and Central America.

DR. AHLBERG describes, in Neubert's *Deutsches Magazin*, the Japanese flora as being at the height of its beauty in May. None of the great families is without its representatives, although as usual the Cruciferæ, Compositæ, Papilionaceæ, Ranunculaceæ, and Umbelliferæ predominate. The forests are marked by a variety of maples, numerous representatives of the oak, and a large number of varieties of ilex.

UNDER the title of "African Poisons" the *Journal of Applied Science* for the current month has some notes on the poisonous properties of a species of *Strychnos* and on the Inée poison (*Strophanthus hispidus*). Regarding the former it seems to be employed as an ordeal by the natives in Gaboon under the names of "Cusa" or "Icaja," and at Cape Lopez by that of "M'boundou." The plant producing it is described as growing in swampy or inundated situations, and attaining a height of only from four to six feet. The root is long and tapering, and is covered with a red bark, and it is from this bark that the active principle is obtained. The root-bark is scraped off and steeped in about a quart of water. When the water has acquired a reddish colour the poison is ready. According to the recent investigations of Messrs. G. Picholier and C. Saint Pierre the toxical principle of M'boundou is soluble in water and alcohol, and has a mode of action analogous to nux vomica, that is to say, acting on the sensitive nervous system. It only in a secondary degree affects the active nervous system. It is suggested in the article from whence the above information is obtained that it would be interesting to compare the M'boundou with the hoang-nan (*Strychnos gautheriana*) of Cochin China, which is employed in cases of leprosy and hydrophobia.

IN the British Section of the Paris Exhibition, amongst scientific instrument makers, the gold medal has been awarded to Messrs. A. Légé and Co., for their exhibit of instruments of precision and for the improvement of navigation.

WE learn that Parts I. and II. of Mr. Buchanan's work on "The Grasses of New Zealand," which is being published in the colony is on the eve of publication if it has not already appeared. These two parts contain twenty-one plates. The volume is large quarto and when completed will consist of five parts, and will contain fifty-five plates all native printed. It is said that Dr. Hector intends to bring out a reduced edition in octavo with the plates reduced by photo-lithography, and tinted. In this form it will be more handy and convenient than the original bulky volume.

THE Paris mint has published statistics on the value of pieces struck in the establishment from 1795, the date of its foundation, to 1878:—In gold, about 8,500,000,000 francs; in silver, about 5,510,000,000 francs; in copper, about 62,702,785 francs. Total value, 14,072,702,785 francs.

PROGRESS OF THE "CHALLENGER" REPORT[1]

AS a period of more than two years has now elapsed since the return of the *Challenger* expedition, I may very properly be expected to give some account to my scientific brethren of the progress which has been made up to the present time in the reduction and classification of the multitude of observations which were made in different departments, in the description and illustration of the natural history collections, and in the preparation of the official record of the voyage, which has been called for by government.

Before doing so, however, it may be well for me to sketch briefly the circumstances which led to the adoption of the plan now in operation for working up the results of the expedition, and putting them in a permanent form.

The voyage of the *Challenger* was undertaken for a very definite purpose, the determination of the physical and biological conditions of the ocean, and as the period of three years and a half occupied by our cruise round the world was quite too short even to draw the first outline sketch of general deep-sea conditions, our time was entirely devoted while the ship was at sea to registering observations, and cataloguing, and labelling, and storing specimens. Owing to the great liberality of the government in supplying abundantly all the necessary materials and appliances, an enormous collection of marine animals was sent home from time to time in wonderfully good condition. It was a matter of distinct understanding when I undertook the scientific direction of the expedition, that the responsibility not only of the conduct of the scientific work during its progress, but of the working out of its results at its close rested with me, and before the end of this cruise I was called upon by the Lords Commissioners of the Admiralty for a statement for their consideration of the course which I proposed to pursue both with regard to the publication of the results, and the ultimate destination of the specimens and other materials. Of course I had given this matter much careful thought, and I was in a position to submit to their lordships a general plan which commended itself to their approval, and which is now in process of being carried out unaltered. I proposed that for the time the collection should be placed in rooms which were given to us for the purpose in the University of Edinburgh, and that for the first year our attention should be chiefly directed to the preparation of an outline of the general report, and to the examination of the collection and its rough classification in zoological sequence; and that during this period the services of the gentlemen who had been associated with me on the scientific staff on board should be retained. I proposed that as soon as possible arrangements should be made to invite gentlemen who were recognised as authorities in different departments, and who had sufficient leisure at their disposal, to undertake the description of the zoological series, group by group, and that a sufficient sum should be granted to defray the expense of complete illustration and to compensate them to a certain extent for their expenditure of time.

With regard to the destination of the collection, I proposed that in the first place each specialist who undertook the description of a group should be requested to set aside all unique specimens

[1] "On the Progress which has been made in the Preparation of the Official Report of the *Challenger* Expedition." Paper read at the Dublin meeting of the British Association by Prof. Sir C. Wyville Thomson. Revised by the Author.

and the most complete series possible of all species of which there were duplicates to be sent at once to the British Museum, and that afterwards duplicates should be arranged in sets, and distributed to museums at home and abroad, according to a scheme to be sanctioned by their lordships.

Many considerations entered into the selection of the experts, into whose hands this vast collection of new material was to be placed. As I was solely responsible to Government for the general result, I was of course obliged to undertake this duty; but I rarely trusted my own judgment, acting in most cases with the advice and sanction of one or other, the weight of whose opinion on the special question at issue would be universally recognised. My sole object was to carry out the task intrusted to me to the best of my ability, and to prepare and to submit to Government the most complete report possible, and I asked the co-operation of men who, in my judgment, were the most likely to insure this result. I have to acknowledge, with profound gratitude, the frank readiness with which almost every appeal for assistance was responded to, and it is a matter of great satisfaction to me that the plan of work, which is the result of these arrangements, has elicited an expression of general approval from nearly all of those to whose opinion on such a question I attach the highest value.

From what I see at present the official account of the voyage of H.M.S. *Challenger* may be expected to extend to from fourteen to sixteen quarto volumes of 500 or 600 pages, the whole illustrated by about 1,200 lithographed plates, and many charts, woodcuts, and photographs. The MSS. of the first volume, which will contain a general account of the voyage, the hydrographic details contributed by Staff-Commander Tizard, the head of the Naval Surveying Staff on board, is nearly completed, and the charts of the ship's course and the sections showing the vertical distribution of ocean temperature which illustrate this volume, are in course of preparation. The second volume will consist chiefly of tables, and will include a report on the magnetic observations made during the voyage, drawn up under the superintendence of the Hydrographer to the Navy; and a detailed report on the meteorology, prepared by Capt. Tizard. The greater part of this volume is already in print, and I place before you a copy of the Magnetic Report, which will give an idea of the general appearance of the book.

Another volume will contain the discussion of the nature and composition and source of the deposits forming at the bottom of the sea, the composition and specific gravity of the sea-water, and the proportions of its contained gases, and sundry other questions, chemical and physical; and the remainder of the work will be occupied by a series of memoirs by different authors on the various groups of animals which constitute the deep-sea fauna. A large number of these monographs are in progress, and I hold in my hand a series of about 150 plates of natural objects which are now on the stone.

Only one department is finished; and I have here to record my special obligation to my friend Mr. Thomas Davidson for a most complete and thorough memoir on the *Brachiopoda* of the expedition. Mr. Davidson has not only figured all the species himself with the utmost care, but he has added to his descriptions of the *Challenger* forms a discussion of the relations which they bear, in structure and distribution, to all other known living forms, which greatly enhances the value of his monograph.

The illustration of the *Foraminifera* has been undertaken by Mr. Henry Brady, and a rapidly-thickening pile of plates testifies to the diligence of his artist, Mr. Hollick.

This plate represents several forms of a remarkable little group of Rhizopods in some ways intermediate between the Foraminifera and the Radiolaria, to which we have given the name *Challengerida*, as the twenty or thirty species of which the group is composed seem hitherto to have escaped observation.

A splendid memoir by Prof. Haeckel, on the *Radiolaria*, is in progress, and will be illustrated by upwards of a hundred plates. Everyone acquainted with Haeckel's classical work, "Die Radiolarien," will appreciate our good fortune in having secured his co-operation.

The next series of plates prepared under the direction of Mr. Moseley represent the deep-sea corals, and the next series, also by Mr. Moseley, illustrate a most remarkable series of coralloid forms of *Hydrozoa*, on whose structure and relations Mr. Moseley's careful work during the voyage and since our return has thrown quite unexpected light. The normal *Hydrozoa* are in the hands of Prof. Allman, but owing to our having already secured for other departments the services of nearly all the available British artists experienced in natural-history drawing, he has not been able as yet to make much progress. Prof. Haeckel will describe the deep-water *Medusæ*, few in number, but of the highest interest.

Echinodermata are very abundant in the abyssal region. I have undertaken to describe a portion of the first class of this type, the Stalked Crinoids, and upwards of twenty plates are on the stone, illustrating their structure. The drawings are by Mr. William Black, one of the most successful students in the Edinburgh School of Art under the Science and Art Department, and now an accomplished natural-history draughtsman. And Mr. Herbert Carpenter takes up the *Comatulidæ*, a group rich in undescribed species, which he is studying, along with the valuable collection procured by Prof. Semper in the Philippines.

Prof. Alexander Agassiz is progressing rapidly with the *Echinidea*, and his monograph, exquisitely illustrated as all these American memoirs are, will probably be among those first finished. Mr. Lyman is working at the *Ophiuridea*, which he says are very numerous and almost all new, and I expect Mr. Théel, of Upsala, to come over shortly to examine the *Holothuridea*, which he is going to describe under the general superintendence of Prof. Lovén. The Swedish Arctic Expeditions have already yielded some of the most characteristic abyssal forms of this group, and these we know through the excellent memoirs of Mr. Théel.

This bundle of beautiful plates drawn under the eye of Mr. Busk, illustrate the *Polyzoa*, a group which descends to the greatest depths, represented by many undescribed and characteristic genera.

Dr. McIntosh is working out the *Annelida*, and will require a volume to himself, while several hands are occupied with the *Crustacea*, Mr. Spence Bate taking the heaviest part of the work in the *Macroura*, Prof. George Brady describing the *Copepoda* and *Ostracoda* with many beautiful plates, some drawn by himself and others with the assistance of artists; and Prof. Huxley dealing with the *Anomoura*, which some of his recent investigations have given for him a special interest. Mr. R. Boog Watson undertakes the lower *Mollusca*, a heavy task involving the steady work of a year or two, and a ponderous volume, in which he receives the friendly assistance of our colleague, Dr. Gwyn Jeffreys, Mr. Edgar Smith, and other conchologists here and elsewhere; and Prof. Huxley closes the Invertebrates with a monograph of the *Cephalopoda*, culminating in a gem of a memoir on the structure of *Spirula*, the drawings done by his own hand from the careful dissection of the single specimen which we procured.

Brief descriptions of the deep-sea fishes have already been published by Dr. Günther, and the final memoir is in preparation; the birds in which group rhere are a comparatively small number, are in the charge of Dr. Sclater; and some anatomical details involving important additions to our knowledge of the structure of the *Cetacea*, the *Marsupialia*, and the Penguins have been worked out by Prof. Turner, Prof. Morrison Watson, and Dr. Cunningham.

It will be seen that in the foregoing notes many important groups of marine invertebrates are still unaccounted for. These are cases in which it has not yet been found possible to commence work from want of artists or some other cause, or in which the naturalists engaged have not yet reported progress. I have every hope that all will be under way in the course of another year.

Perhaps I have said enough to show that a report is in progress of preparation, which may be expected to register in a suitable form the results of a great scientific expedition. Some causes of delay have occurred, and there has been the regulation amount of friction inseparable from the working of a complicated piece of machinery, but my feeling is that on the whole things are going on wonderfully well, and the utmost I anticipate is the necessity for a little extension of time for the appearance of the later volumes.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE

DR. MANSFIELD MERRIMAN, author of the "Elements of the Method of Least Squares," and for several years past an instructor in the Sheffield Scientific School of Yale College, has accepted the Professorship of Civil and Mechanical Engineering

in Lehigh University, Bethlehem, Penn., and enters upon his duties there at the beginning of the September term.

WE noticed recently the death of Prof. Behn, president of the Kaiserliche Leopoldina-Carolina Deutsche Akademie der Naturforscher. The Academy has chosen as his successor for a term of ten years, Prof. H. Knoblauch, of Halle, well known by his researches on light. With this new election, the head-quarters of the Academy are changed from Dresden to Halle.

SCIENTIFIC SERIALS

American Journal of Science and Arts, July.—In his ninth paper of "Contributions to Meteorology" (based chiefly on observations of the U.S. signal service), Prof. Loomis shows, *inter alia*, that barometric waves often travel from the Pacific Coast across the Rocky Mountains (10,000 feet) and reach the Mississippi valley with but little modification. Areas of unusually high pressure in their course eastwards are generally accompanied by areas of low pressure both on the east and west sides, and at an average distance of about 1,200 miles. When a centre of low pressure has passed the wind sets in with force from the north, and being deflected westwards by the earth produces condensation there. Again, it is shown that an area of low barometer in Ireland is usually accompanied by one of high barometer in Southern or South-eastern Europe, and that during the colder months Vienna is generally near the centre of this high area, which is replenished by air rising from the area of low pressure.—Mr. Goldmark finds, from experiment, that a rise in temperature produces a slight but constant increase in the electric potential of the air.—A new and remarkable mineral locality (for manganesian phosphates) in Fairfield County, Connecticut, is described by Messrs. Brush and Ed. Dana. No less than six new and well-defined species have been got from it, besides many other known but rare species. All the minerals are obtained from veins of albitic granite.—Prof. Mayer claims independent invention of the sound-mill (lately described by M. Drorak); Mr. Chester describes some artificial crystals of gold and gold amalgam, and Prof. Rood suggests a form of telephonic relay.

August.—This opens with the first portion of an interesting lecture by Prof. Asa Gray on "Forest Geography and Archæology." The forest production of America is sketched and considered in its relation to climatic conditions.—Prof. Leconte gives an account of the structure and origin of mountains, and answers some recent objections to the "contractional theory."—The presence of a solid hydrocarbon in the trap-rocks of New Jersey Mr. Russell accounts for by infiltration of petroleum into cavities and subsequent evaporation and (to some extent) oxidation.—Prof. Trouvelot gives an account of his observations of the recent transit of Mercury at Cambridge, Mass. Among other points noted are the luminous ring round Mercury observed distinctly for more than two hours, and the rounding off of the angles formed by the sun's limb with Mercury after internal contact, a phenomenon of the same nature as the black drop (which was not seen).—Prof. Peters indicates the position of the new planet he discovered lately.

SOCIETIES AND ACADEMIES

GENEVA

Physical and Natural History Society, June 6.—Prof. F. A. Forel, wishing to explain the action of the seiches of the Lake of Geneva, seeks to establish the effects of storms, which often coincide with marked oscillation of the fluid mass. He is still continuing his investigations.—Prof. Schift described his researches on the alterations which the blood undergoes in consequence of a momentary arrest of the circulation.—M. Phil. Plantamour has studied periodical displacements in the air-bulb of improved levels manufactured at Geneva and placed in the cellar of his house. At certain times there is shown a slow change towards the east, without sensible return towards the west; at other times the immobility is complete. The maximum of eastern elevation takes place sometimes towards 5 P.M., at other times sooner, towards mid-day, with oscillations the amplitude of which does not exceed seventeen seconds.

July 4.—M. Eug. Demole presented phenomena of oxidation produced by the free oxygen of the air. Thus the case was presented of dibromic ethylene.—Prof. Forel, by increasing the rate of the unrolling of the paper of his limnograph, has attained interesting traces corresponding to the perpetual oscillations of the level of the Lake of Geneva. These oscillations vary from half a minute to two or three minutes in maximum, corresponding neither with the duration of the waves nor with those of the seiches. They vary notably in intensity with the agitation of the lake by the wind or by a steamer, but their cause is yet totally unknown.

VIENNA

Imperial Academy of Sciences, July 11.—The following among other papers were read:—On the nature of galvanic polarisation, by Dr. Exner.—Optical investigation of spark-waves, by Prof. Mach and Dr. Gruss.—On the optical properties of soot, by Dr. Rosicky.—Researches on the origination of chlorophyll-granules, by Dr. Mikosch.—On two new isomeric cyanide acids, by Herr Herzig.—On the elastic reaction in glass, by Herr Klemencie.—On the composition of cinchonin, and on its oxidation products, by Dr. Strauss.—Action of oxidising agents on some hydrocarbons, by Herrn Othman and Zeidler.—On camphor chlorides, by Dr. Spitzer.—On a camphene derived from camphor, and the synthesis of its homologues, by the same.

PARIS

Academy of Sciences, September 2.—M. Fizeau, president, in the chair.—The following papers were read:—Formation of a cylinder out of a circular disc, by M. Tresca.—Litter manure, by M. Ch. Brame.—On the influence of the quantity of blood contained in the muscles on their irritability, by M. J. Schmoulewitsch. The author has proved that the muscles, on becoming anæmic, do not lose their irritability at once; on the contrary, it increases for some time, and having attained a certain degree, begins to decrease.—On the existence of an intra-Mercurial planet observed during the solar eclipse of July 29, by Prof. Watson. M. Gaillot is investigating the results of Prof. Watson's observations.—On the diffusion of cerium, lanthanum, and didymium, by M. Cossa.—On the causes of the humming of insects, by M. J. Pérez. The author finds that among hymenoptera and diptera, humming is due to two distinct causes; one, the vibrations of which the articulation of the wing is the seat, and which constitute the true hum; the other, the friction of the wings against the air, an effect which more or less modifies the former. Among the powerful-winged lepidoptera, such as the Sphinxes, the sweet and mellow hum of these insects is due only to the rustling of the wings by the air. This sound, always grave, is the only one produced; it is not accompanied by basilary beatings, on account of a peculiar organisation, and especially on account of the presence of scales. Among the Libellula, the base of whose wings is provided with soft and fleshy parts, there does not exist true humming, but a simple noise due to the rustling of the organs of flight.—Application of borax to researches in vegetable physiology, by M. Schnetzler.

THE LINKS OF THE ANIMAL WORLD

Les Enchaînements du Monde Animal dans les Temps Géologiques, Mammifères, Tertiares. Par Albert Gaudry. 8vo. (Paris: F. Savy, 1878.)

UNDER this poetic title Prof. Gaudry has added one more to his valuable works on the fossil mammalia of the Tertiary Period. Some sixteen years ago he carried on the explorations on the classic ground of Pikermi, which proved that the plains of Marathon were haunted by antelopes, gazelles, giraffes, and hipparions, in the upper miocene age, while the forests then overshadowing rocky Attica sheltered the mastodon and rhinoceros, and yielded food to innumerable monkeys (Mesopithecus) allied to the Barbary ape. During the last five years he has been painting a like picture of the upper miocene mammalia of Mont Léberon, in which, as in Pikermi, the remains of the animals are preserved in an abundance and a perfection somewhat like those discovered in the Western States, by Prof. Marsh. The two elaborate quartos on these discoveries are now followed by an elegant octavo full of woodcuts, treating of the links that bind together some of the more important groups of tertiary and living mammalia. In it the author deals with the European mammalia without treating exhaustively the accumulation of facts brought to light by Marsh, Hayden, Leidy, and others, in the American eocenes and miocenes. Nor are these as yet published in sufficient detail to allow of their being worked into the book before us. The impression made upon my mind by the vast stores of remains in the museum at Yale is one of profound melancholy; for so numerous and varied are the mammalia that many years must elapse before they can be brought into complete relation with those of Europe. Up to the present time the fragmentary notices which have appeared bear the same relation to the systematic treatment to be expected from Prof. Marsh, that isolated *tesseræ* bear to the whole design of a mosaic. Prof. Gaudry, therefore, has acted well in confining his work mainly to the Tertiary mammalia of Europe.

Our author approaches his subject from the point of view offered by evolution, by taking some of the more salient characters of a group, and tracing their "descent with modification," in passing from older to newer stages of the geological record. The fishes passed through the principal phases of their evolution in the Primary, the reptiles manifested their most extraordinary modifications in the Secondary age, and at its close had settled down into that equilibrium which they now present, while the mammalia were being unfolded, form after form—"en pleine évolution"—in the Tertiary Period. In the opening chapter the relation of the marsupials to the placental mammals is discussed, and our author concludes, from the results of embryology, that the former must have preceded the latter, and that the imperfect and helpless condition of the young, nourished in a marsupium, or taking refuge on the back of the mother, would be a serious obstacle to rapid increase, since the young would be likely to be drowned in the passage of rivers or arms of the sea in migration in search of food. This may have been one of the causes of their being supplanted by the placental mammals at the beginning of the Tertiary Period, as they would be heavily weighted in the struggle for life by this condition. The elimination of the marsupial herbivora from the Tertiary fauna of Europe and America might have been produced by the migration rendered necessary by the great geographical and climatal changes at the close of the cretaceous age. It is a significant fact that the only living mammalian genus found in the eocene age is the tree-haunting Didelphys, which took refuge probably in the forests, and held its place in Europe as late as the lower miocene age, and which still holds its own in the warmer parts of America as the sole representative of a Secondary marsupial fauna once in possession of the European and American continents. There are, however, traces of a marsupial fauna other than those offered by Didelphys, to be seen in certain *intermediate forms*. The Hyænodon of the eocene and lower and middle miocene, and the eocene Pterodon, were carnivores combining the dental formula of four true molars (three of which are carnassials), and three premolars of the *Thylacinus*, with the characters of an ordinary placental carnivore. The dentition of the lower eocene Palæonictis is remarkably like that of the Tasmanian Dasyure, and the lower miocene Proviverra unites a marsupial dentition and brain with the ordinary viverrine attributes. These marsupial characteristics can only be accounted for on the hypothesis that they have been handed down from a marsupial ancestry, and they render the conclusion highly probable, that all the placental are descended from the implacental carnivores.

Prof. Gaudry points out that the rhinoceros and the palæothere are probably descended from common ancestors, and shows the gradual modification of skull, and evolution of horns in the former animal. In the middle miocene a hornless rhinoceros (Aceratherium) appears, and is accompanied in the upper miocenes of Eppelsheim by a small horned species, of which it is probably the female. As we pass upwards to the pliocene the horn becomes more highly developed, and the nasal bones more strongly built, until we arrive at a maximum in the pleistocene *Rhinoceros tichorhinus.* We believe that the horn was originally a male character transferred ultimately to the female in the way pointed out by Mr. Darwin.

In like manner, also, our author traces the evolution of horns and antlers in the ruminants. The earliest representative of the order, if it be a representative, is the hornless Xiphodon of the upper eocenes. Horns come in in the middle miocene, and in the upper attain a considerable development, as in the antelopes. We may add that, in Europe, the bovine development of horns arrived at its maximum in the gigantic bisons and uri of the pleistocene, while in the pliocene of Italy there was a bos without any horns—a fact which renders it probable that the polled cattle produced by domestication is merely a case of a reversion to an ancestral type fostered by the care of man. None of the lower miocene deer possessed antlers. In the middle miocene they are bifurcated, as in the Muntjac; in the upper they are still small, and with three or more types; in the pliocene they pass through the stages presented by the

Axis and Rusa, ultimately culminating in the wonderfully complex antlers of *Cervus Sedgwickii* of the forest bed, and *C. dicranios* of the Val d'Arno, and in the gigantic antlers of the pleistocene, and pre-historic Irish elk. It must, however, be pointed out that the *Cervus Matheronis* of the upper miocene, identified by Prof. Gaudry with the Axis, has no relation with that animal, as may be seen by the examination of the most perfect antlers yet discovered of the former animal, in the British Museum. A more rudimentary form of antler (*Procervulus*, Gaudry) even than the Muntjac has been discovered in the middle miocene strata of Thenay, without a burr, which was, like ordinary horns, persistent through the life of the animal.

We have merely touched upon some of the questions raised in this work, which occupies most important ground in the evolution controversy, and may be looked upon as one of the first fruits of the principles laid down by Mr. Darwin in the "Origin of Species."

W. BOYD DAWKINS

AMERICAN GEOLOGICAL SURVEYS

United States Geological Exploration of the Fortieth Parallel. By Clarence King, Geologist in Charge. Vol. II. *Descriptive Geology*, 1877. Vol. IV. *Ornithology and Palæontology*, 1877. (Washington: Government Printing Office, 1877.)

THE important survey of a portion of the north-western states of America, which was commenced by Clarence King and his able assistants in 1867, has now, after ten years of arduous labour, been brought to a close. In the original scheme drawn up for the publication of the results of this survey it was proposed that the observations of the surveyors should be published in five volumes, devoted to the following subjects:—

I. Systematic Geology.
II. Descriptive Geology
III. Mining Industry.
IV. Zoology and Palæontology.
V. Botany.

The third of these volumes was prepared and issued soon after the commencement of the survey. It abounds with valuable details concerning the rich ore deposits of the north-west and the methods by which they can best be worked. It is difficult to know which to admire most—the accuracy and beauty of illustration of this volume or the characteristic energy and promptitude with which it was produced in order to meet a pressing want.

In 1876 a supplementary volume numbered VI., not contemplated in the original scheme, was published; it deals with the subject of Microscopic Petrography, and is from the pen of Prof. Zirkel, of Leipzig. As this work has already been noticed in the pages of NATURE, we need do no more on the present occasion than refer to the circumstances under which it was published.

Two other volumes, those numbered II. and IV. are now before us, and amply sustain the high reputation which Mr. Clarence King and his indefatigable fellow-workers have acquired for energy and zeal in the prosecution of their important task, no less than for great geological knowledge and literary ability.

The volume on Descriptive Geology consists of a series of chapters giving full and accurate accounts of the geological features of the Rocky Mountains, the Green River Basin, the Utah Basin, the Nevada Plateau, and the Nevada Basin respectively, the descriptions being from the pens of Arnold Hague and S. F. Emmons. The rocks exposed in this vast area include representatives of the whole series of geological formations from the Archæan to the Post-pliocene, together with many plutonic and volcanic masses belonging to various geological periods. The descriptions are of the most minute and careful character, and are interspersed with valuable analyses of the rocks described.

One of the most useful features of this volume is the series of twenty-six lithographic plates illustrating the grand and peculiar scenery of the district. These are admirable copies of photographs taken upon the spot, and they are probably, without exception, the most successful attempts to illustrate scenery in this manner that have ever been made. We would especially instance Plates V. and VI., illustrating the Tertiary bluffs near Green River City, Wyoming, and Plate XIV., showing the characters of the Wahsatch Limestone Cliffs, Provo Cañon, Wahsatch Range, as presenting the characteristic features of rock-masses in a manner which cannot fail to be appreciated by every geologist who has had opportunities for extensive observation in the field. Other plates, such as X., representing the Agassiz Ampitheatre in the Uinta Mountains, and XIX., in which a ridge of Archæan quartzite in the Humboldt Range is depicted, are wonderfully striking reproductions of the remarkable scenery of the district. In a series of plates illustrating the saline springs, we have the peculiar features of the great plains also presented to us in a very vivid manner.

Volume IV. consists of three parts. In the first of these a series of fossils from all the formations, from the Silurian to the Tertiary inclusive, are described by the late F. B. Meek. This part is illustrated by seventeen lithographic plates of great excellence. The second part is by James Hall and R. P. Whitfield, and describes certain new forms, from the Primordial to the Jurassic; it is illustrated by seven plates.

The third part of the volume is devoted to the description of the habits of the various species of birds met with during the several expeditions. It is from the pen of Mr. Robert Ridgway, the zoologist attached to the staff.

The United States Government is to be congratulated on having been able to secure such valuable illustrations of the natural history of their extensive and interesting territories as are contained in the splendid volumes before us, and the value of these contributions to science is greatly enhanced by the liberality with which they have been distributed among scientific workers and public libraries in every part of Europe. We shall look forward with much interest for the appearance of the other volumes of the series.

J. W. JUDD

OUR BOOK SHELF

Tent Work in Palestine. A Record of Discovery and Adventure. By Claude Regnier Conder, R.E., Officer in Command of the Survey Expedition. Two vols. (London: Bentley and Son, 1878.)

THIS is the first substantial result of the survey of Palestine, which has been going on for the last few years. It

is published by the Committee of the Palestine Exploration Fund, but is merely preliminary to the publication of the various detailed memoirs and the unprecedentedly minute map which are in preparation. It is mainly the narrative of Lieut. Conder's personal work and adventure, but besides its strong interest as a record of adventure in one of the most interesting countries in the world, it contains a vast amount of information and discussion concerning the many places so full of sacred associations to all Christian peoples. The work of the Survey was often pursued under considerable hardships, and occasionally at some risk, and more than one of the staff had to succumb during the progress of the work. It is evident that this most interesting of surveys has been executed with a minuteness and a care that leave little to be desired. The survey was actually commenced at the end of the year 1871. Capt. Stewart, the first officer in charge, had to come home on account of his health, and in July, 1872, Lieut. Conder took up the command, and completed four-fifths of the survey, the remaining fifth being carried out in 1877 by Lieut. Kitchener. The great map now extends over 6,000 square miles, from Dan to Beersheba, and from the Jordan to the Mediterranean Sea. This map is being prepared in twenty-six sheets; and an idea of its minuteness may be obtained from the fact that it will show tombs, caves, cisterns, wells, springs, rock-cut wine-presses, remarkable trees, and even the Roman milestones. Accompanying the map will be a memoir prepared by Lieut. Conder under the direction of Major Wilson and Mr. George Grove. It is hoped that all will be ready for publication in the course of a few months. This memoir will contain a vast collection of varied information gathered from many sources, and with the map will undoubtedly be of infinite service to students of the Biblical narratives. Lieut. Conder's work will amply repay careful study, and the many illustrations of places whose names are "familiar as household words," add greatly to its interest and value.

LETTERS TO THE EDITOR

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.

[The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to ensure the appearance even of communications containing interesting and novel facts.]

Discovery of Vulcan

A LETTER from the Astronomer-Royal, in NATURE, vol. xviii. p. 380, giving the exact position of θ Cancri on the day of the total solar eclipse, intimates that, as the position given by Prof. Watson of the intra-Mercurial planet discovered on that day agrees so closely with that star, it may have been the object discovered, I have thought it advisable to give the facts concerning it, in order to correct such an impression if it still exists. That he had a view of the planet as stated there is no doubt, for I myself saw it some four or five minutes later, using θ as a comparison star, and am able not only to corroborate the discovery, but to substantiate the position given by him. Its proximity to θ enabled me to estimate its position with great exactness, especially in declination. It may be well here to state that I was prevented from searching to the east of the sun, in consequence of forgetting to untie a string with which I had tied, to the eye end of the telescope, a long pole to prevent the wind from shaking it, the end resting on the ground not allowing the instrument to be moved to the eastward. It is undoubtedly to this circumstance, which at the time seemed untoward, that I owe the discovery of Vulcan. In my eagerness to discover this hypothetical planet I had decided to ignore nearly all of the phenomena attending the eclipse, and as, at the commencement of total phase, there was visible neither the chromosphere nor any protuberances—nothing, in fact, but the corona, I almost immediately began the sweeps for it; but my hampered telescope behaved badly, and no regularity in the sweeps could be maintained. Almost at once my eye caught two red stars about 3° south-west of the sun, with large, round, and equally bright discs, which I estimated as of the fifth magnitude, appearing (this was my thought at the time) about as bright in the telescope as the pole star does to the naked eye. I then carefully noted their distances from the sun and from each other, and the direction in which they pointed, &c., and recorded them in my memory, where, to my mind's eye, they are still distinctly visible. I then swept southward, not daring to venture far to the west for fear I should be unable to get back again, and soon came upon two stars resembling in every particular the former two I had found, and, sighting along the outside of the tube, was surprised to find I was viewing the same objects. Again I observed them with the utmost care, and then recommenced my sweeps in another direction, but I soon had them again, and for the third time in the field. This was also the last, as a small cloud hindered a final leave-taking just before the end of totality, as I had intended. I saw no other stars besides these two, not even δ, so close to the eastern limb of the sun. The distance between them was about 7′ or 8′.

By three careful estimates the two stars pointed exactly to the sun's centre. When it is considered that a deviation of not over 15″, in two objects so close, will cause them to point considerably to one side of the centre of the sun—three degrees away—it may be assumed that its declination was quite correctly estimated. Thus far all seems clear and free from doubt, but it is just here where the trouble begins, for, unfortunately, I could not tell which was the star and which the planet. Happily Prof. Watson comes to the rescue, and with his means of measuring, says "the planet was nearest the sun."

The Astronomer-Royal gives the place of θ, on that day, as in R.A. 8h. 24m. 40s., Decl. + 18° 30′ 20″. From this I deduce the position of the planet at 5h. 22m. Washington M.T. to have been in

R.A. 8h. 26m. 40s.
Decl. + 18° 30′ 25″.

This is a close approximation to that given by Prof. Watson. It is to be hoped that a comparison will determine the position in its orbit, whether it was approaching superior conjunction, as Watson thinks, or, as appears most reasonable to me, had just passed its inferior conjunction.

LEWIS SWIFT

Rochester, N. Y. September 4

The Respiration of Plants

I DESIRE, with your permission, to give publicity in the columns of NATURE to the results of some observations on the above subject, communicated by me to the Royal Society of Victoria on June 13. As the facts to be mentioned are not referred to in Sachs' "Text-book of Botany," in the dictionaries of chemistry of Watts and Wurtz, or in recent volumes of the *Journal of the Chemical Society* or the *Chemisches Centralblatt*, I presume that they are little, if at all, known to botanists. I have found, first about nine years ago, and have more systematically observed lately, that fresh sections of many fruits, such as the apple and pear, and other vegetable structures as the potato, turnip, &c., give the reactions considered to be characteristic of ozone, viz., causing separation of iodine from iodide of potassium, and turning tincture of guaiacum blue, the intensity of these reactions varying in different samples of the vegetable substances, but depending mainly on their comparative freshness. I have further found that the same structures contain a substance which acts as an *Ozonträger*, to use Schönbein's expression, a substance which transfers ozone from peroxide of hydrogen and similar articles. This is shown by the fact that if the guaiacum is not blued at all, or only to a slight extent, the blue colour becomes very marked when a drop of ethereal solution of peroxide of hydrogen is added. I infer from these observations (1) that the oxygen inhaled by living plants, and even by pulled fruits for a time, is ozonised or rendered active, probably by entering into loose combination, as is the case with the oxygen in the blood of animals; and (2) that it is probable, though not proved, that the ozone-transferring substance existing in almost every fresh vegetable structure is that with which it is loosely combined, as the oxygen in the blood is with the hæmoglobin of the red corpuscles, which is a very active *Ozonträger*. This element in plants is gradually destroyed as decay comes on, and ceases to perform its

ozone transferring function when the fruit, &c., containing it is cooked. It is not chlorophyll, as is shown by its situation, and it seems to be intimately associated with the vascular tissue. From analogy with the animal substances hæmoglobin, fibrin, myosin, &c., which have a similar action, it may be presumed to be proteinaceous, though I am unable to indicate its chemical and other characters more exactly. The interesting analogy between the respiratory functions of animals and plants indicated by these observations will, I hope, be considered a sufficient excuse if I ask you to insert this short summary of my paper which you will receive at the same time. JAMES JAMIESON

Melbourne, July 6

The Electro-Magnet a Receiving Telephone

THE experiment of Mr. F. G. Lloyd, described in NATURE, vol. xviii. p. 488, is simply a repetition of Page's original experiment, the basis of all telephony. The electro-magnets of ordinary relays and Morse apparatus make capital telephone receivers when their armatures are screwed up, and it is a common thing for operators at intermediate stations in America to enjoy the music that is being transmitted between the terminal stations during some telephonic display. I remember the station-master at Menlo Park telling me that the music sent from New York and received at Philadelphia was heard, much to his surprise and delight, all over his little wayside station. The effect is dependent upon the strength of the currents flowing. With a Riess' transmitter sending musical notes and voltaic currents it can be made very loud. With an Edison or a Hughes transmitter the effect is much less, and with a Bell transmitter it is almost, if not quite, inaudible.

Electro-magnets also can be used as transmitters, because their iron cores invariably contain some residual magnetism.

September 16 W. H. PREECE

Rayons de Crépuscule

IN your issue of July 25, Mr. Abbay, in writing of Ceylon, says that, as far as he is aware, the *rayons de crépuscule* are never seen in the low country.

Allow me to add the weight of my testimony to that of Mr. Pringle, given in NATURE of August 1.

During a residence of about five weeks here, the rays have been noticed from twelve to fifteen times, and I have been told by an old resident that their appearance is very common.

This country is the perfectly flat alluvial land and marsh bordering the Gulf of Mexico, whose shores are distant about eight miles from our camp.

On fully half of the occasions have the bands been traced from the sun, without break, to the point in the east, 180° from it. The rays are seen best when the sun is very near or below the horizon. On the evening of August 16, the display was exceptionally beautiful. The sun had set behind a bank of dense cumulus clouds, while the remainder of the heavens was covered with very faint cirro-cumulus clouds. A band of dark blue spread from the sun, and after widening to about 85° near the zenith, converged to a point either in, or slightly below the horizon. This was the cloud's shadow. In the south a line about 15° wide, and in the north, one about 80° wide, were lighted up, and shone with brilliant tints, varying from rose to orange. The lines between the deep blue of the shadow, and the lighter blue, mottled with the shining, closely packed cloud flecks, were sharply marked, as sharply, indeed, as the arch in the Aurora, which it called to mind. I have noticed the phenomenon several times in Maryland, in a gently rolling country, but nowhere have I seen it as often and as distinctly as here.

JULIUS KRUTTSCHNITT

Morgan's La. and Texas R. R. Camp, St. Mary Parish, Louisiana, August 24

"LES rayons de crépuscule" seem not to be of uncommon occurrence. They presented a most superb spectacle at this place last Sunday evening. The weather had been extremely warm all day and the mountains were seen through a thick haze. At sunset masses of dark clouds, fringed with gold, lay along the horizon to the west, while beyond them the sky was of a beautiful pink. As the sun sank lower many bands of pink appeared, stretching from the west entirely across to the east, appearing broader and paler, of course, near the zenith. They changed gradually in width, position, and number for perhaps half-an-hour, and then disappeared. Their changeableness indicated that they were due to clouds near the horizon.

Sing Sing-on-the-Hudson, September 3 H. S. CARHART

The Microphone

THE form of microphone described by Mr. Gerald B. Francis (NATURE, vol. xviii. p. 383) is easily made and very efficient. It not only did for me all its inventor promised, but with a common tumbler inverted over it upon the sounding-board so as to prevent direct impact of sound waves upon the ball, it became a powerful transmitter of the human voice. I conversed easily and satisfactorily with a friend a half-mile from my end of the wire. The exact contact of the lower wire with the ball was effected by a screw with a very fine thread passing through without touching the lower block or cup. The voice must be kept low to prevent bounding of the ball so as to break contact. Bell telephones were used as receiving instruments, the batteries being Hill and Calland gravity batteries used extensively in this country upon telegraph lines. These batteries agree exactly in every respect with the one used by Prof. Hughes in his interesting experiments excepting the clay, which is not necessary, and must be a great inconvenience in a permanent arrangement. A White Swallow.—Albinism in Birds

BY the side of a steep sand-cliff overhanging a stream—the Cambeck, in Cumberland—I lately saw, on a glorious summer afternoon, a white swallow flying about with many other birds of the same species. A most beautiful bird it was; perfectly snow white, with perhaps a slight tinge of blueish grey near the roots of the tail-feathers. In size it seemed to be rather smaller than the swallows around it; but in its flight and pursuit of insects there was no noticeable difference. From my position at the top of the cliff I could often see the bird within a very few yards of me.

Like the grouse of which Sir Joseph Fayrer writes in NATURE (vol. xviii. p. 518), this white swallow is, I believe, of considerable rarity. I have been able to hear of only one, seen many years ago near Repton, in Derbyshire; and in numerous works on British and other birds which I have consulted, I cannot find any very precise mention of a white variety. Magillivray remarks of the *Hirundo riparia*, the species to which the bird I saw belonged, that "individuals of a whitish colour are said to occur, but I have never met with any remarkable deviations from the ordinary appearance." Yarrel speaks of a white variety of the common swallow as not uncommon; while of the same swallow, or *Hirundo domestica*, several varieties are recorded by Buffon, and among them the white, there being "no country in Europe where these have not been seen, from the Archipelago to Prussia."

Able to catch flies on a cloudless summer day, this white swallow can, I hardly think, have been an albino, although I had no opportunity of such close inspection as Sir Joseph Fayrer had of the grouse he shot near Dunrobin. Albinism in birds must, I should imagine, be altogether unknown or unobserved, for I can nowhere meet with any account of it. Undoubted albinos are sometimes spoken of as "white varieties"—an albino monkey is, or lately was, so labelled at the Zoological Gardens; and it is possible that this very general term may include some cases of albinism, even among birds.

The Hearing of Insects

I AM not aware if it is generally known that there is a wasp in South America which seems to present undoubted evidence of a faculty to hear, or it may be to feel, and distinguish certain vibrations of sound.

The wasp is a common one on the Guayaquil River; a large slender black species, much feared on account of the virulence of his sting, which not unfrequently produces fever. I, myself, though little susceptible to the bites of mosquitoes or flies, and the stings of scorpions, &c., when once stung on the finger by

a "cubo," as this wasp is called in Ecuador, had my whole hand and forearm considerably swollen for a couple of days.

A common spot chosen by the cubo for his nest is high up on a palm stem at the river-side, and natives are well aware of the danger of uttering any loud cry when in its proximity. I have frequently experimented by giving a shrill whistle—his particular abhorrence—from a safe distance, with the invariable result of all the wasps flying in confusion from the nest in manifest anger.

It is said that there is a wasp in New Granada in whose proximity one dare not speak, but for this I cannot vouch, and very possibly this may be an exaggerated account of the cubo. It would certainly be a dangerous experiment to speak loud when very close to a cubo's nest, even on the Guayas, and a shrill voice would be sure to irritate the wasp. ALFRED SIMSON

Circulating Decimals

IN NATURE, vol. xviii. p. 291, is an extract from a letter by Mr. R. Chartres, in which is given a remarkable property of certain circulating decimals. Mr. Chartres only refers to fractions of the form $\frac{1}{nr - 1}$ (where $r = 10$); but I have since found that a somewhat similar property belongs to other fractions when expressed as circulating decimals.

For instance, $\frac{1}{7} = \dot{1}4285\dot{7}$; here we observe that the last figure of the circulator is the same as the denominator of the vulgar fraction; moreover, by multiplying the 7 by 5, we get the next figure, and this by 5, taking in the remainder, gives the third from the end, and so on till we get the whole recurring decimal.

So far this is somewhat similar to Mr. Chartres' discovery, but now observe the curious property in the following fractions:—

$$\frac{1}{7} = \cdot\dot{1}4285\dot{7}$$
$$\frac{1}{17} = \cdot\dot{0}58823529411764\dot{7}$$
$$\frac{1}{27} = \cdot\dot{0}3\dot{7}$$
$$\frac{1}{37} = \cdot\dot{0}2\dot{7}$$

In each case the last figure of the circulator is the same as the unit figure of the denominator of the vulgar fraction. Now the multipliers which give the remaining figures are, for the first fraction, 5; for the second, (5 + 7); for the third, (5 + 14); for the fourth, (5 + 21); and generally to convert a vulgar fraction of the form $\frac{1}{nr + 7}$ ($r = 10$) to a circulator, we put down the last figure 7 and multiply successively by $7n + 5$.

For fractions of the form $\frac{1}{nr + 3}$ the multiplier is $3n + 1$, and the last figure 3.

For fractions of the form $\frac{1}{nr + 1}$ the last figure in the circulator is 9, and the multiplier is $9n + 1$.

Of course the last figure must be that one which, multiplied into the unit of the denominator, and the unit of the result being subtracted from 10, leaves a remainder of 1.

These rules added to that of Mr. Chartres include every case of fractions which, when reduced to decimals, circulate.

Littlehampton, Sussex EDMUND P. TOY

Autophyllogeny

WITH reference to the note in NATURE on autophyllogeny in a leaf of *Papaya vulgaris*, I wish to place on record another freak which I have more than once noticed in the Papeea or Papeeta, as we call *Carica papaya* out here. The plant is diœcious, the female being stumpy and her flowers and fruit sessile; the male plant, on the other hand, is tall and graceful, and the flowers depend from long stalks. The freak I have above alluded to *consists in the presence of distinct and well-formed fruit on the male plant*, and I regret I was unable, on both occasions, to secure the anomalous production for examination. The Sea-Serpent Explained

THE letters of Dr. Drew and others remind me of what I witnessed at Sandgate twenty-four years ago. I was staying at a cottage on an elevation which commanded an extensive sea-view. One morning my attention was called to a large, dark, undulating body, which moved rapidly through the sea. As it was some way out from shore, I naturally concluded it to be of enormous length. I lost no time in making inquiries as to the nature of this phenomenon, and was so fortunate as to discover a fisherman who had witnessed it. He told me it was a flight of petrels. But for this I should certainly have believed that I had seen the Great Unknown. I have often seen a similar phenomenon, but nothing nearly so striking as this.

Valentines, Ilford, September 16 C. M. INGLEBY

RECENT PROGRESS OF SELENOGRAPHY

THE most active period in the study of selenography during late years is comprised between two epochs, that of the announcement of a change in the crater *Linné* in the year 1866 by Dr. Schmidt, Director of the Observatory at Athens, and that of the announcement of a new crater north-west of Hyginus, by Dr. Klein, of Cologne, in the year 1877. The years elapsed between the two events above-mentioned have been characterised more or less by the manifestation of considerable interest in lunar studies, of which the projection of a map of the moon 200 inches in diameter, to have been constructed under the auspices of the British Association for the Advancement of Science was the first indication. Of this map, four sections embracing an area of 100 square degrees of lunar latitude and longitude have been published, containing all the formations known in 1866–1868 to exist on this area, each of which is separately catalogued. Three of these sections, with catalogues, were published in the *Reports of the British Association* for 1866 and 1868; the fourth was published by the aid of a private subscription, in 1870. We are not aware that much use has been made of these areas and catalogues in endeavouring to ascertain if the 433 objects chronicled in them retain the characteristics they possessed in the above-mentioned years. It was a part of the duty of the Committee appointed by the Association to receive the reports of volunteer observers who undertook to examine the objects in certain subzones at stated intervals, which resulted in the addition of several new objects to those originally published, but nothing has been effected in this direction since the Committee was not reappointed in 1868.

In February, 1869, a map of the Grey Plain, the *Mare Serenitatis*, was published in the *Astronomical Register* for that month, by Messrs. Joynson and Williams. It contained several new objects not on former maps, and was followed in the course of a few months by a map and monogram of the same region. The map was divided into the British Association areas, and it contained 277 objects, each being distinguished by a British Association symbol; they were briefly described in a table of the areas in which any part of the Mare was found.

The four areas of the British Association map on a scale of 200 inches to the moon's diameter accompanied by a monogram of the formation *Hipparchus* on a scale of 100 inches, with that of the *Mare Serenitatis* form a collection of maps, which, with the descriptions of 710 separate objects embody the conditions of those portions of the moon's surface which were telescopically or photographically examined between 1866 and 1870. As placing in the hands of the student a body of facts especially suitable for future reference, these maps and monograms will furnish most important information on the condition of objects recorded on or in them during the four years above mentioned. It is in the future the real progress of the past is more truly measured.

In the years 1871 and 1872, Reports of a Committee appointed for discussing observations of lunar objects suspected of change, was read before the British Association for the Advancement of Science, the principal results being the discovery of about thirty-six spots and

crater cones upon the floor of the walled plain *Plato*, which were very variable in visibility; also of several streaks which were not only variable in visibility but also in form; the most usual shape that was observed was that of a trident on the south-west part of the floor. There appeared to be a close connection between the spots and streaks, but its nature was not mentioned in the reports further than a surmise that the appearance of certain streaks appeared to be coincident with an increased visibility of certain spots. Another result was a brightening of the north-west floor, for a time only, as well as a brightening of several of the streaks, but perhaps the most important was that of a *darkening* of the darker parts of the floor as the sun rose higher above its horizon. This result has been most strenuously controverted by a popular writer, who alleges that the effect observed was due only to contrast. Be this as it may, the Report for 1872 is explicit as to a gradual darkening with increased solar altitude; at any rate the same writer bears testimony to the exceptional care with which the floor was scrutinised.

In the year 1876 (May) Neison's "Moon and the Condition and Configuration of its Surface," appeared. It marked an era in selenographical research, the English student having within his reach, for the first time, a description of the principal formations on the moon's surface in his own language. This work, of 576 pages, includes a map drawn in twenty-two sections, the principal formations on each being fully described in the body of the work. Besides the purely topographical part, the author has given five introductory chapters in which he has treated of the physical condition of the surface, the general characteristics of the lunar formations and the variations that have from time to time been detected on the surface. He has also given a most lucid chapter on the history both of the progress of mathematical investigation and selenographical research as regards the moon.

The most important recent event in the progress of selenography was the discovery, on May 19, 1877, by Dr. Klein, of a dark spot which he described as "a great black crater full of shadow without a wall north-west of Hyginus," (NATURE, vol. xviii. p. 197). It was first announced by him in his *Wochenschrift für Astronomie* for March, 27, 1878, and has since been seen by several observers who have generally confirmed the appearances mentioned by him, and also agree in their testimony that no such spot existed formerly in the region in which it was seen. In the celebrated case of Linné the information in 1866-67, as regards the *former* condition of the surface of the moon was so imperfect that it was considered by astronomers that "no change in Linné could have taken place, but that Lohrmann, Beer and Mädler, and Schmidt must have been mistaken." [1] A considerable controversy on this subject occurred during 1867-68, but nearly six months have elapsed since Dr. Klein's announcement, and we have not heard of his discovery having been seriously questioned. It is true that a certain white spot, alleged to have been found on photograms taken within the last fourteen years, has been regarded as indicative of the existence of Klein's crater during those years, and from the probability of its locality being that of Klein's crater, the conclusion has been drawn that the latter is not new. Admitting that a somewhat similar spot existed thirteen years ago, the real nature of which we are unacquainted with, and which may have disappeared in the interim, we are quite as much in the dark as to the real nature of the change ascertained to have taken place by Klein, as to the former existence of the spot discovered by him; both await further elucidation.

The recent publication of Schmidt's large map of the moon in twenty-five sections indicates the latest era of progress. If selenographers apply themselves energetically to examine it, the study of the moon's surface will make great progress; but for this purpose much self-denying labour is indispensable, as the map contains as many as 32,856 craters, exceeding those recorded by Mädler by 25,121. It is important for the true progress of selenography that all of these newly-recorded craters should be observed in such a manner as to leave no doubt of their existence. To effect this each observer should keep his record of observations in the form of a catalogue. In the earlier part of this article we have alluded to the plan adopted by the British Association, viz., of cataloguing every object inserted or to be inserted on its map, and we have also alluded to those publications which contain the descriptions of 710 objects. We believe that a comparison of those publications with Schmidt's map is in progress, and that some of the objects in them are not in Schmidt's map. It is, therefore, certain that, indefatigable as Schmidt has been, if we regard his map as perfect we shall make a great mistake. May we rather endeavour to add to the already large number of objects which he has chronicled.

[1] Neison. "The Moon, and the Condition and Configuration of its Surface," p. 125.

HYDRO-INCUBATION [1]

WE wish that Mr. Christy had used a less barbarous term for his useful apparatus: that, however, is of little consequence to practical men.

At a time when our native farm-yard and dairy produce only supplies about two-thirds of what London and our secondary and third-rate towns need, anything that will assist the unready Saxon in so unsatisfactory a state of things ought to be received with gratitude.

Fowls, in a dietetic point of view, are, we are satisfied, certainly of much more importance than is ordinarily supposed. Let any thoughtful medical man in general practice think what a comfort it would be to him if well-fed young fowls were available for the poorer among his patients, and he will agree with us that such an apparatus as Mr. Christy's may become a great boon. That the masses of the people should be able, in time of illness, to purchase useful wine, the more delicate kinds of fish (such as whiting and soles), fresh eggs, and succulent and tender poultry—these are things desirable to a degree only known to those who are familiar with the treatment of diseases in the homes of the common people. Many a kindly Family Doctor passes from house to house heavy-hearted as well as (too often) overworked; the sad answer to his advice as to regimen being, again and again—"It is easy, Sir, for you to prescribe, but how can we afford these luxuries."

The old remark as to the value of an improvement in the grazing department of the farm, that should "make two blades of grass grow where only one grew before," is now more than ever pertinent. Let our readers look at the Registrar-General's returns for London only, especially in a very healthy season, such as last year, and he will see that the number of the births weekly, as compared to the deaths, is such as to add about *two thousand* hungry mouths to the population in three weeks. Then from all the provinces men and women are pouring into London and the large towns, where they need in the closer air more and better food than would have sufficed them in the country. Therefore we are glad to see energetic merchants like Mr. Christy, bestirring themselves to see what new cattle-food can be found from other climates, and how our rural people can be stimulated and helped to grow and develop for their own benefit and for the benefit of others, food of many kinds that shall be as "manna" to thousands and myriads of hungry people.

But there is another, and much more limited, sphere in which such an apparatus as the "hydro-incubator," will

[1] "Hydro-Incubation in Theory and Practice." By Thomas Christy, F.L.S. Second Edition. (London: 1878.

be of the greatest value. The readers of NATURE will appreciate anything that helps the scientific worker. Now, at last, we are going to the root of things in biology, and only the embryologist knows fully what a boon an egg-hatcher, convenient and easy to work, would be. The eggs of the hen will be wanted in their various stages of incubation, as long as there are workers in these departments, but many other sorts of oviparous animals have to be worked out in all their stages besides the common fowl. Snakes, lizards, tortoises, crocodiles, all these are rivals of the bird in their embryology, and of many kinds the eggs could be procured and their embryos developed if the worker had some such apparatus as Mr. Christy is bringing out. We want, not merely the general embryology of these ovipara, such as is so excellently illustrated and described in Messrs. Foster and Balfour's work, but the special development of any important organ ought to be traced in all its stages through not one, but many types of the vertebrata: through *all* the principal kinds indeed.

Some of us are trying to do this in the skeletal structures; the nervous system, still more important, wants an army of workers, then there are the respiratory, digestive, excretory, and generative organs, all these want a complete history in all their stages, not in one type merely, but in scores of types. We therefore wish well to all energetic and enterprising men who put it into our power to work on a wider scale; such means and appliances as can be brought out by men too restless for close and patient study, may be of infinite service to the close and patient student, who is too dreamy and abstracted to invent for himself.

W. K. P.

NOTES ON SOME NATAL PLANTS

GROWING plentifully among the grass on the coast hills of Natal is a small blue flower belonging to the Rubiaceæ. In this plant, generally speaking, there are two forms only, in one of which the five stamens are exserted considerably beyond the tube of the rotate corolla, and the stigma is included in the tube; in this form the tube is almost devoid of hairs. In the other common form the position of these essential organs is reversed, the stigma protruding to about the same extent that the stamens do in the first mentioned, and the stamens being included; here, however, the upper part of the corolla tube is *thickly* covered with downy hairs—of course this is an ordinary dimorphic plant. But I find lately a third form of the same species (only, however, rarely) in which both stamens and stigma are exserted and are of the same length, so that here self-fertilisation must take place, as the stamens and stigma touch at the time the former dehisce. I do not think this can be termed a cleistogamic form, as, although rather smaller and lighter in colour than the others, the difference is only trifling. The hairs which cover the corolla-tube in the form with included stamens serve to keep the pollen collected near the upper part of the tube, as, if it fell to the base it would not be so easily transferred by the proboscis of an insect as when lightly held by the hairs through which the insect must make way. As these hairs would be for this purpose useless when the stamens are exserted they do not occur in the other form.

I notice the same arrangement of hairs in another dimorphic plant belonging, I think, to the same order, which grows on the marshy flats near the sea. I have found on the coast lands here four other plants, in which cross-fertilisation is secured by dimorphism, one of them being a monocotyledonous plant.

There is a species of *Polygonum* which climbs in the bush which well illustrates another plan ensuring cross-fertilisation; while the flower is young and the perianth still closed, enveloping the immature stamens, the three branching stigmas protrude from between the segments in a fit state to receive the pollen. If (as is usual) the ripe stigmas were only exposed when the flower opens, although the evils of self-fertilisation would of course be avoided by the plant being proterogynous, still, as it is wind-fertilised, the perianth and stamens would be in the way of any stray pollen-grains reaching the stigmas; while as it is, nothing interposes between pollen and stigmas.

Lately I have found a curious aberration of form in *Tecoma capense* growing here. It is very common in the bush, forming great beds of bright colour, and normally has a scarlet trumpet-shaped corolla, with one rudimentary and four perfect stamens. I found, however, three or four plants growing within a short distance of each other, in which there were eight perfect stamens; they seemed, however, to have been formed at the expense of the corolla, for there was only one segment coloured at all, the remainder being colourless and small. The ovary seemed in several cases to have been fertilised. The ordinary form of this plant, although individually so brightly coloured, growing in large numbers and secreting much nectar, is seldom or never visited by Lepidoptera. It is, however, frequented by honeysuckers and small bees in numbers. All through the day you can hear the shrill chirp of the small bright honeysucker among the blossoms. The immediate reason why butterflies and moths do not visit it I cannot give; but the stamens and stigma (which are beneath the large upper segment of the corolla) are long, and so high above the opening of the corolla-tube that those insects, in visiting the flower for its nectar, would not be at all certain to touch either, and so in comparison to the honeysucker and small bees would be of little benefit to the plant; for when the former of these visits the flower the feathers of his head are just of the height to brush off the pollen, and the latter in collecting the pollen is equally certain to distribute it, as the bifid stigma is about the same length or only slightly longer than the stamens. Can the nectar have been modified to suit the taste of the useful honeysucker without reference to the useless butterfly?

Natal, June 27 M. S. EVANS

PHYSICS IN PHOTOGRAPHY [1]

III.

THESE last experiments were remarkable in another point of view, as they opened out the question as to whether the salts of silver might not prove sensitive to rays to which they had been supposed hitherto to be insensitive. Silver iodide, for instance, when exposed to the spectrum in a solution of potassium sulphite proved sensitive as far as "*a*" of the spectrum instead of stopping short at the point indicated in Fig. 2 (p. 529); and silver bromide in the molecular grouping which absorbed the red proved sensitive to a wave-length of somewhere near 11,000, whereas in its normal state 9,600 was its limit.

Similarly silver chloride proved sensitive to an extent which presumably may be increased till it is equal to that of the bromide. In both these instances we have a proof that the compound was sensitive to these abnormal rays, and that the image formed by those rays was destroyed as soon as formed by their oxidising action giving an undevelopable form of salt. It may be remarked that by exposing films in reducing solutions such as ferrous sulphate, and pyrogallic acid rendered very slightly alkaline, that an image can be developed as fast as it is formed.

The natural outcome of the experiments on the oxidation of the photographic image just narrated is that it should lead to the solution of the problem of photography in natural colours, such as that of Becquerel, Niepce de St. Victor, and others. In the fourth edition

[1] Continued from p. 531.

of Hunt's "Handbook of Photography," we read, at p. 161, "Niepce de St. Victor has made many experiments to produce the colours upon salts of silver and copper spread upon paper, but without success; the metallic plate appears absolutely necessary, and the purer the silver the more perfect and intense is the impression." The following is recommended as the most effectual mode of manipulating:—"The plate is highly polished with tripoli powder and ammonia; being perfectly cleaned, it is connected with the battery and plunged into the bath prepared in any of the ways stated. [The baths were made from ferric chloride, cupric chloride, hydrochloric acid, &c.] It is allowed to remain in the bath for some minutes, taken from it, washed in a large quantity of water, and dried over a spirit-lamp. The surface thus produced is of a dull neutral tint, often almost black; the sensibility of the plate appears to be increased *by the action of heat*, and, when brought by the spirit lamp to the cerise red, it is in its most sensitive state."

"The sensibility, however, of the plates is low—*two or three hours* being required to produce a decided effect in the camera obscura. . . . These, when I first saw them, were perfectly coloured in correspondence with the drawings of which they were copies, but the colours soon faded, and it does not appear as yet that any successful mode of fixing the colours has been discovered." The coloured spectra which Becquerel photographed were produced in a somewhat similar way, the variation from which need scarcely be repeated.

In Hunt's work we also find that natural colouration of photographs was found to be possible by one or two other processes, but that the above gave the most satisfactory results. Mr. Simpson also noticed when using an emulsion of silver chloride and after exposing the film to white light so as to tint the surface with a lavender colour, that he was able to reproduce on the film the tint of different coloured glasses to which such a surface might be exposed.

It will be noticed that the coloured spectra were produced on a dark compound of silver which gradually responded the colour falling on it. We have first a case of total or nearly total absorption of all the rays, and a subsequent production of compounds of varying tints. In order to produce any variations of colour it is only necessary that we should have at the most three molecular groupings, one of which should absorb the blue and green, another the green and red, and the last the red and blue. Whether the number of groupings may be reduced to two is a question for future consideration. In Lockyer's note read before the Royal Society on June 11, 1874, "On the Evidence of Variation in Molecular Structure," we find statements which might have been conceived to be almost too bold at the time when they were made, but which subsequent investigations seem to prove to be exact. In this note he refers to definite molecular groupings of compounds and the absorption caused by them, and indicates that we may have a group which will absorb at the blue end and another which will absorb the red end of the visible spectrum. It has already been shown that the silver bromide can be reduced to two groupings, one absorbing the blue and the other the red, and it is somewhat remarkable that, by applying pressure to the latter molecular grouping, it is gradually resolved into the former grouping, and passes through all tints of spectrum between the blue and the red. It must be remembered that these colours are not the colours of thin plates, but are totally independent of the thickness of the film so long as light can penetrate through it. It is not too much to assume that if silver bromide can be made to group itself into these two states, that the sub-bromide when oxidized should also assume a similar molecular condition. With this compound in a state which practically absorbs all rays, it is easy to imagine that particular sets of vibrations may cause it to resolve itself into groupings which answer to them. We have, in fact, the inverse of the reduction of the silver bromide by different portions of the spectrum. It is found that one molecular grouping can be reduced by a whole series of vibrations; thus the blue absorbing molecular group is altered by all the radiations from the ultra violet to the yellow, and the red absorbing molecular group by the radiations from the ultra-red to the green. If there were a green absorbing molecular group, of which there is a strong suspicion of the existence, it would probably be altered by radiations from the blue to the orange. If, then, one silver compound can exist in two or three states of molecular grouping, it is quite within the range of reason that the oxidised compound should exist in the same three groupings. The black compound to which we have already referred, in fact, does arrange itself thus, probably by a re-arrangement of molecules, as formed when it absorbs oxygen. If a plate be prepared in a similar manner to that described above, and if it be exposed in an oxidising medium, these groupings are attained rapidly, a few minutes sufficing where previously hours were required. The images thus formed, however, appear not to be unchangeable, as exposure to white light, or to any colour except that in which the re-arrangement takes place causes the colours to fade. The feat of producing *permanent* photographs in natural colours is as yet unsolved, but it may not be so far distant as may be imagined. In order to obtain them it is necessary that a method should be found by which the molecular groupings of metallic silver can be formed in either of the two (or three) states already described. As is well known, the absorption by metallic silver in a thin film takes place entirely in the red end of the spectrum, but it is a fact well known to photographers at large, that in certain processes it is perfectly feasible to obtain silver in which the transmitted light is of a pink red colour, whilst tints varying from indigo, passing through olive green to rich brown are familiar. In order to obtain permanent photographs in natural colours, the object to be sought is a method by which the sensitive silver compound may be reduced by the red rays to a molecular grouping, which on development (probably by the alkaline method) shall be grouped into the red transmitting molecular grouping, and so on. When this is discovered, the leap between monochromatic pictures, and chromatic, will have been taken, and the once apparent improbability have become more than a possibility.

We have finally to return to the subject of photography with the light of those rays which are usually inactive upon sensitive salts, and at which we have already glanced.

To Dr. H. Vogel, of Berlin, is undoubtedly due the new interest which has been taken in this branch of photography. Towards the end of the year 1873 he announced that he had discovered a method of making the non-actinic rays in certain circumstances actinic. We quote his own words[1]:—"I have found that bodies which absorb the yellow ray of the spectrum make bromide of silver sensitive to the yellow ray. In like manner I find bodies which absorb the red ray of the spectrum make bromide of silver sensitive to the red rays. For example, by the addition of *corallin*—which absorbs the yellow ray—to a bromide of silver film, it becomes as sensitive to the yellow ray as to the blue ray." In articles which he published at various times he enlarged on this idea, some of his most striking experiments being conducted with aniline dyes of various kinds. He and Waterhouse have shown that a silver bromide film becomes sensitive to the part of the spectrum which certain of those dyes absorb, whether the absorption be due to a compound formed between the dye and silver, or to aqueous or alcoholic solutions. This at once opened

[1] *Photographic News*, December 5, 1873.

out a large field for inquiry, and made research in this direction doubly interesting owing to the fact that apparently certain physical laws would have to be modified if Vogel's theory were correct. He divided the action of the substances so added into two, the dye he called an optical sensitiser for that particular part of the spectrum which it absorbed, whilst bodies which absorbed the halogen (thrown off by the reduction of the molecule) he called a chemical sensitiser, and a combination of both properties in a dye made the film sensitive to the absorbed rays. The theory of the optical sensitiser seemed to clash with the received notion of molecular motion, but before analysing the results the accompanying figure should be studied, which is taken from Vogel's work on Photography (Fig. 5).

Let us take one or two examples from the above figures and see whether they agree with Vogel's assumption. We will take VIII. as a standard of comparison, being the effect on unstained bromide, and this will be fair (though it does not take the form given, shown in Fig. 2, p. 529), as it is presumed that this sample of bromide was worked with throughout. Comparing say IV. with VIII. we see that in the blue the sensitivenesses, as shown by the ordinate of the curved line, are very similar, but that the action is got in the yellow. In examining cyanine blue, the dye used, we find that the absorption takes place just at that part of the spectrum. Similarly examining V. and VI. we arrive at the same results, and in fact the absorption of the rays invariably corresponds with the photographic action.

It will be seen then that without doubt the principle Vogel contends for might explain the phenomena. He, however, found that if the silver bromide film had been prepared with an excess of bromide, that the actions indicated did not take place. This seemed to indicate a weak spot in the theory, and it pointed at first sight to the idea that it was necessary to form a coloured compound of the dye with silver, in order to render it sensitive. In the majority of cases this still seems to be, if not a necessity, yet a cause of increase of sensitiveness to the region of the spectrum absorbed. Vogel, however, shows that, if the silver bromide film, prepared with an excess of bromide, be washed, and be then treated with a dye, and a chemical sensitiser, such as tannin, that the same action takes place. The theory of a silver compound in this case must evidently be abandoned, and would point to

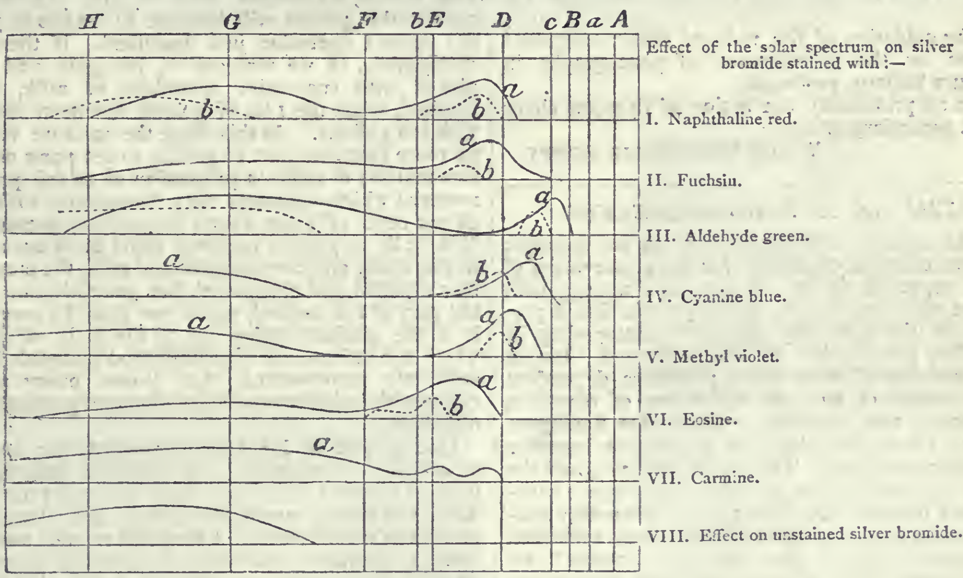

FIG. 5.

The curves marked *a* show longer exposure than those marked *b*.

the correctness of Vogel's theory, did not other experiments in a certain degree offer an explanation more accordant with our preconceived ideas. Let the dye be mixed with *plain* collodion and a film of it be exposed to the spectrum, it will soon be visibly evident that there is a marked effect produced by the rays absorbed. Thus cyanine blue will be found bleached in the region near D and below it. If over the dyed film of collodion thus exposed, a film of silver bromide in collodion be poured in the dark, and the alkaline developer be applied gradually, a silver image of the altered portion of the dyed collodion film will make its appearance, although the film of silver bromide has received no impression by light. The explanation of this remarkable phenomenon is to be found in the theory of alkaline development already given in these articles. The reduced dye acts as a nucleus on which the metallic silver will first adhere, and this first reduction of metallic silver determines the position which the further reduced silver shall occupy, and thus the image is built up. When there is an excess of soluble bromide in the film the developing action will be retarded. This series of experiments seems, then, to indicate that there is no need for optical sensitisers to alter the oscillation of the molecules or molecular groups, but that, in some instances, the same theory may be applied to the action of dyes as may be applied to the deposition of metallic silver on a glass plate which has not been freed from "dirt," a disagreeable phase which is well known to photographers at large. The explanation of the diagram is, therefore, not hard to understand when viewed in this light. The theory of rendering the silver salt sensitive to the red has already been explained, and the same explanation is naturally applicable to those dyes which, when brought in contact with silver, form a definite compound with it.

There are many interesting physical researches which spring out of these various experiments, amongst which may be mentioned a method of determining the size of atoms and their arrangement in the molecule, and last and not least, the production of permanent photographs painted in natural colours by light itself. The attempts made of late to form photographs in proper colours by taking distinct negatives through blue, through green, and

through red media and then printing positives from such, and finally obtaining red, green, and blue prints and superimposing them, is not a step in a scientific direction, since it is utterly impossible to secure monochromatic colours which are pure enough to give the truth of nature. Such efforts, though they may be commercially valuable, yet are not to be followed with too much zeal by scientific photographers.

We may now axiomise the results we have indicated:—

1. That the undeveloped photographic image on a silver compound is formed by the reduction of that compound.

2. That the compound may exist in two (or three) molecular groupings.

3. That the compound can only be sensitive to the rays which it absorbs.

4. That the reduced silver compound may be rendered incapable of development by combining with oxygen.

5. That light of every refrangibility may cause an acceleration of oxidation provided the compound acted on absorbs such light.

6. That the oxidation of the compound reduced by any particular ray may be as rapid as the reduction, and thus to give a false idea of their limit of sensitiveness to the spectrum.

7. That the oxidation of the reduced silver compound may account for the phenomenon of photographs in natural colours hitherto produced.

8. That in all probability the action of dyes on silver bromide is a secondary one.

W. DE WIVELESLIE ABNEY

GELATIN AS A FOOD-PRESERVER

REMOVAL of water and exclusion of air are amongst the most effective conditions for the preservation of animal and vegetable foods. If you coat an egg with collodion you may keep it a year, and yet will find it perfectly sound at the last. By dipping a mutton-chop in melted paraffin, putrefaction will be prevented. But in both these examples of preservative processes, dependent upon the exclusion of air, you make use of materials which are costly and uneatable. There are analogous drawbacks to all similar plans for preventing injurious changes in articles of food. The tinning method, and the method of simple desiccation in warm dry air, are satisfactory in their results; but the range of alimentary substances amenable to such treatment is not very extensive. In Dr. Campbell Morfit's new "Gelatin Process" we seem to see several points of superiority over most of the older plans for attaining the same end. It is true that chemists have not been in the habit of looking upon gelatin (or indeed any other similar complex nitrogenous body) as likely to prevent or arrest decay. On the contrary, few solutions afford a more suitable *nidus* for the development of fungoid germs than a liquid containing gelatin. But the experience of a good many months tends to show that food-preparations containing gelatin, if once dried so as not to contain more than 10 or 12 per cent. of moisture, do not become mouldy even when exposed to warm and moist air. A large number of Dr. Morfit's experimental mixtures have been so exposed for some weeks, lying on my office table: yet they have not suffered any decided deterioration. They comprise many perishable foods, such as cabbage, tomato, milk, and meat. Though not of equal merit as specimens of the gelatin process, all are edible, and some positively palatable. Further experiment will doubtless enable the inventor to improve his process by modifying it still further, so as to suit a greater variety of vegetable and animal foods.

Perhaps the best way of explaining the nature of Dr. Morfit's invention will be to take as an illustrative example the case of milk. The mere drying-up of milk has been tried with but moderate success—the resulting powder becoming quickly rancid on exposure to the air. The preserved or condensed milk now in such extensive use is in many respects a satisfactory and convenient preparation, but it is mawkishly sweet, containing more than one-fourth its weight of added cane sugar. Moreover, in consequence of this addition, the proportion of nitrogenous or flesh-forming substances in it has been seriously lowered. Now the substitution of gelatin for cane sugar in preserving milk meets both these objections to ordinary condensed milk. The milk preserves its natural and moderate degree of sweetness, while the gelatin, even if its own value as a nitrogenous nutrient be not considered, certainly does not *lower* the proportion of flesh-formers to heat-givers in the product.

In order to apply his process to the preservation of milk, Dr. Morfit directs us to dissolve 1 lb. of gelatin in 1 gallon of milk at a temperature of 130° to 140° Fahr., and then to allow the solution to set into a jelly; this is then cut into slices and dried. By employing the product of this first operation in lieu of fresh gelatin, for gelatinising a second gallon of milk, a jelly is obtained in which the milk-solids are just doubled in amount. As a gallon of milk contains about 6,400 grains of these solid nutrients, casein, milk-sugar, milk-fat, and phosphates, their ratio to the gelatin will become as 12,800 to 7,000 after the second operation just described. If then the dried *milk-jujube*, as we may call it, be again and again employed with successive quantities of milk, a limit is reached, when the 1 lb. of gelatin has been incorporated with ten gallons. At this stage the mixture will contain no more than one part of gelatin to ten parts of the nutritive matters of milk—a proportion of added preservative material which contrasts very favourably with the 25 to 28 per cent. of sugar found in ordinary preserved milk. If the 1 lb. of gelatin required could be at once dissolved in the whole eight or ten gallons of milk, the process would be simplified and cheapened, but gelatinisation, an essential part of the method, could not then be secured. For it is the gradual drying up of the slabs of jelly, with which the animal and vegetable food-materials have been uniformly incorporated, that leaves every particle of changeable substance with an adequate protective coating of gelatin.

One at least of Dr. Morfit's preparations has become an article of commerce. He dissolves gelatin in lime-juice at a gentle heat, and after removing much of the water and adding sugar, incorporates the mixture with the powder of navy-biscuit. Pressed in moulds and carefully dried, a granular acidulous and agreeable biscuit is produced, which should combine a considerable alimentary value with the anti-scorbutic properties of lime-juice. On analysing the lime-juice jujube, the basis of these biscuits, I find about 8 per cent. of water, 8 of gelatine, 5 of free citric acid, much sugar, and less than 1 (0·7) per cent. of mineral matter or ash. This proportion of gelatin is rather high when compared with the free citric acid, the characteristic ingredient of lime-juice; but the sample analysed was made in April, 1877, and may not represent the exact composition of the recent product. And it becomes a question, whether for travellers' use, it would not be advisable in this preparation to neutralise a little of the acidity of the lime-juice with potash, rather than to mask its presence by an excessive quantity of sugar. Pure lime-juice itself contains very little potash and phosphoric acid or other mineral matter; but that fact affords no argument against the introduction of small quantities of these compounds into such a preparation as that now under consideration.

It would be impossible to discuss in detail the applicability of the gelatin process to the preservation and concentration, in an uninjured, compact, and available form, of fruits, of meat, of cheese, &c., &c. But it may be safely affirmed that Dr. Morfit's invention has already been successfully applied in several directions, and that it is full of promise for the future. A. H. CHURCH

ELECTRIC DISCHARGE IN GASES[1]

II.

THE form of point most favourable to the production of the arc has been minutely investigated by the authors. By turning wires in a lathe to various outlines they arrived experimentally at the best point; this was then placed under the microscope and drawn by means of the camera lucida; from the study of the drawing it was ascertained that the longest spark was procured when the point assumed a form resembling a paraboloid; the curved out

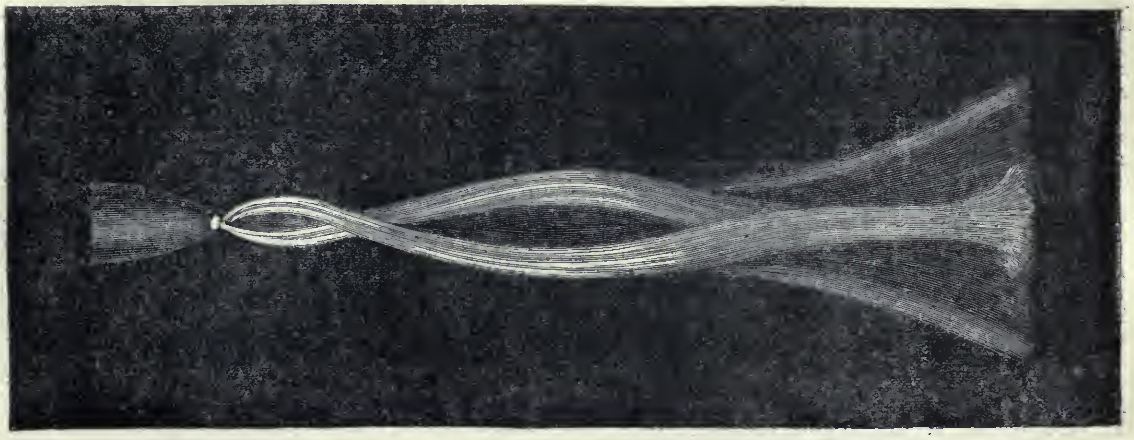

FIG. 8.—"Streamers."

line, which corresponded to that found experimentally, was one in which each succeeding ordinate was in the ratio of the square root of the odd numbers 1, 3, 5, &c., the sectional areas being consequently in the ratio of the odd numbers.

The curves in the diagram (p. 528) show the distances at which, with a given potential, the arc is formed between such a point and a disc, and between two such points respectively. The results recorded in the case of the point and disc are those obtained by electrifying the point to the sign (positive or negative) which gave the greatest length; for it was found that with low potentials the distance at

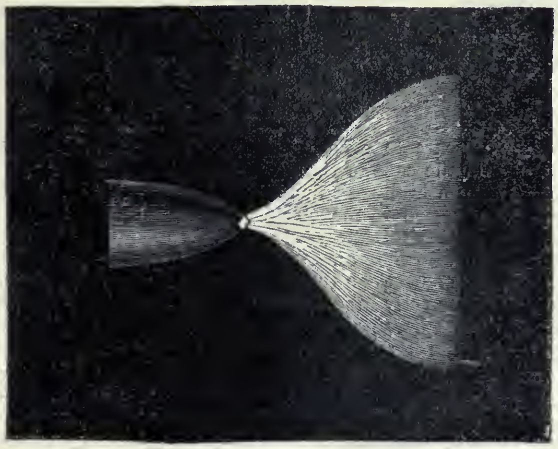

FIG. 9—"Glow."

which the arc forms is greater when the point is *negative*, that between 3,000 and 5,000 volts it is the same whether the point be positive or negative, but that with potentials higher than 5,000 volts it is greater when the point is *positive*.

The actual formation of the arc, when a point and disc or two points are employed as terminals, is preceded by a luminous discharge (streamers and glow), presenting phenomena of an interesting character; an extremely minute quantity of electricity passes as compared to that

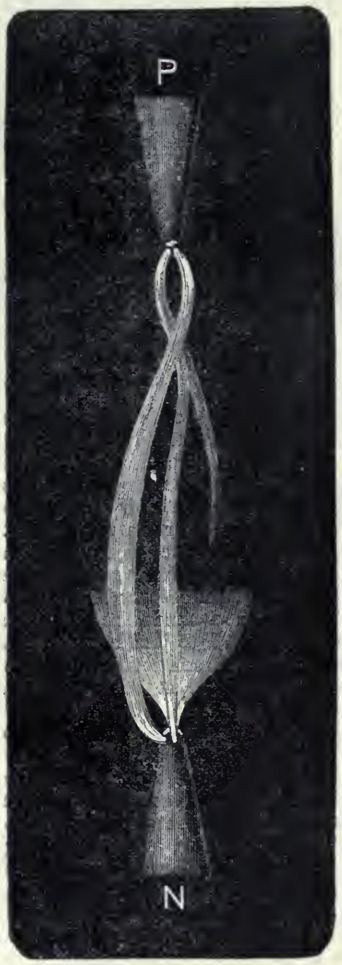

FIG. 10.—"Streamers and Glow."

when the arc is formed, but still it is sufficient when

[1] Continued from p. 528.

caused to pass through a vacuum tube to illuminate it strongly.

"The discharge from the point, when positive, has mainly to the naked eye a stream-like appearance, consisting of a waving line of light surrounded by a very faint sugar-loaf luminosity, and producing a rattling or strong hissing sound; from the point when negative it consists of a glow of light paraboloidal in form, and extending from the point to the disc, but much more brilliant at the point, the noise of the discharge being much less than when the point is positive. The disc, especially when positive, soon becomes covered with a peach-like bloom, and the deposit assumes the appearance of Newton's rings.

"Small as this current is, it is, nevertheless, very manifest from its brightness and the rattling, or loud hissing noise it produces; it frequently continues for some minutes before the spark actually jumps between terminals placed at the striking distance asunder; the streamer-discharge becomes brighter just before the jump and formation of the arc, and this suggested the possibility of particles being carried off in increasing quantity from the point to the disc, and thus contributing to the production of the spark. In order to test this hypothesis, the terminals were placed at the striking distance, and a continuous blast from a blowpipe bellows sent between them; this did not, however, have any effect on the length of the spark, but it deflected the arc when once it had formed.

"Under the microscope the discharge, from the point when positive, is seen to consist of several streams of light, which twist round each other like loosely-bound strands, as shown in Fig. 8, representing the discharge between the terminals, a point and a disc, in a horizontal discharger. Part of the discharge from the point negative is shown in Fig. 9. Fig. 10 shows on a scale of 4 to 1 the phenomenon obtained with 11,000 cells, the streamers and glow proceeding simultaneously from the opposite points of a vertical discharger and existing independently of each other."

In order to study these discharges the authors constructed a microscope (Fig. 11) with a revolving mirror placed at an angle formed by the two tubes composing the body of the microscope, which is bent for the convenience of observation. That part beyond the upright is formed of ebonite, in order to protect the eye from accidental shocks. The discharger used when this microscope was employed was horizontal, as seen in the figure, in order to permit of the employment of the mirror which was mounted on a horizontal axis; the

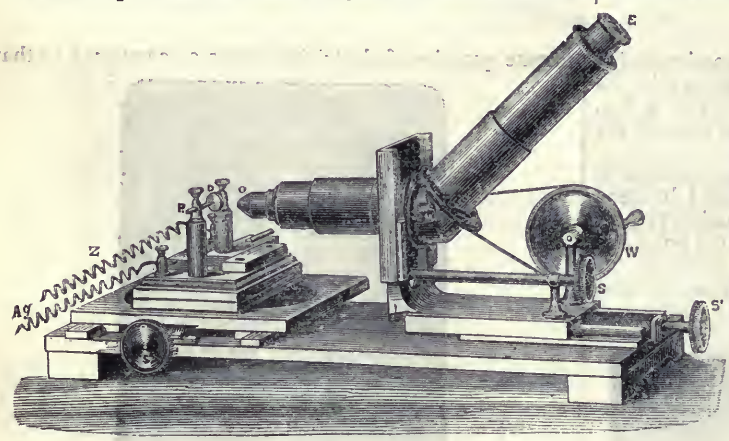

FIG. 11.—Microscope with Revolving Mirror.

FIG. 12.—Analysis of Streamers and Glow.

point P was placed in the fixed upright, and the disc D in that upright which is attached to the adjustable slide. The screw S′ is used to approach or recede the microscope in order to adjust to focus; S″ to bring the point horizontally, and S to elevate or depress the microscope by means of a pinion and rack to adjust the point vertically in the field. O is the object-glass and E the eye-piece; W a multiplying-wheel giving five revolutions of the mirror for one turn of the handle, which may be rotated with ease 200 times in a minute, so that the mirror can be caused to make 1,000 revolutions in a minute, or about seventeen revolutions in a second. The whole framework of the stand is of ebonite, to ensure insulation.

"When the revolving mirror was set in motion it was seen that the streamer-discharge was in reality, to a great extent, intermittent. At times a moderate rotation-velocity of the mirror served to show this by the production of a number of distinct images, as seen in the left-hand drawing in Fig. 12; at others it required the full speed of the mirror. The discharge appeared much more continuous with the point negative: so much so that the image was generally seen in the microscope as a sheet of light brightest near the point, and nearly uniform in a direction at right angles to the axis of the mirror. The right-hand drawing shows the appearance when the point is negative. The difference in the sound emitted when the point is positive and negative respectively appears to afford an additional proof of less continuity in the case of the positive.

"When a high resistance—four megohms, for example—was inserted in the circuit, the character of the discharge was completely changed. Instead of jumping across and forming an arc, a series of brilliant snapping sparks pass between the terminals at more or less rapid intervals, exactly like the sparks from a small Leyden jar; these pierce a piece of writing paper interposed between the terminals, producing minute holes. The spark does not jump at the full distance when the four megohms resistance is inserted; and, to produce an almost continuous succession of intermittent sparks, it was usually necessary to approach the point to 0·30 inch, when, without resistance, the spark with 8,040 cells would jump and form the arc at 0·34 inch."

When charcoal terminals were used the jump of the spark was about the same as with other terminals having a similar shape; the charcoal points could be separated when 8,040 cells were used to 1·25 inch generally, and occasionally to 1·5 inch, without breaking the arc. The arc presented the ordinary characters, as shown in Fig. 13; but that which takes place when the terminals are vertically one over the other is different, on account of its being undisturbed by upward air currents which deflect the arc.

The length of the spark differs in various gases at ordinary atmospheric pressures, but the authors found

that the difference in the length of the spark does not bear any precise ratio either to the specific gravity of the gas or its viscosity in reference to mechanical impulse; they propose to ascribe it, at all events provisionally, to a difference of *electric viscosity*. In order to make experiments on the dge ischarin different gases, they placed the

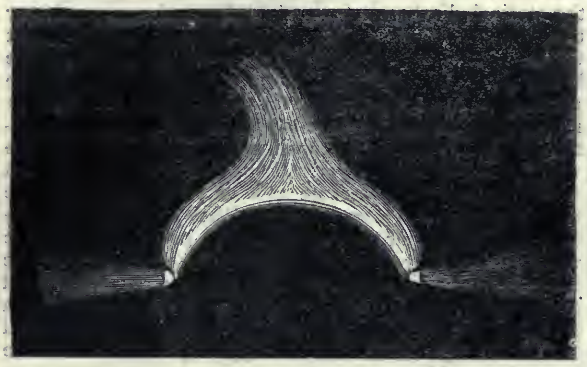

FIG. 13.—Arc between Charcoal Points.

discharger already described (Fig. 4), under a bell glass G G′ (Fig. 14) open at the top and covered with a glass plate P. The glass plate had two screw-clamps which were connected at its under surface with wires led from the screw-clamps *c* and *c′* of the discharger. In connection with these, on the outside surface, were two other screw-

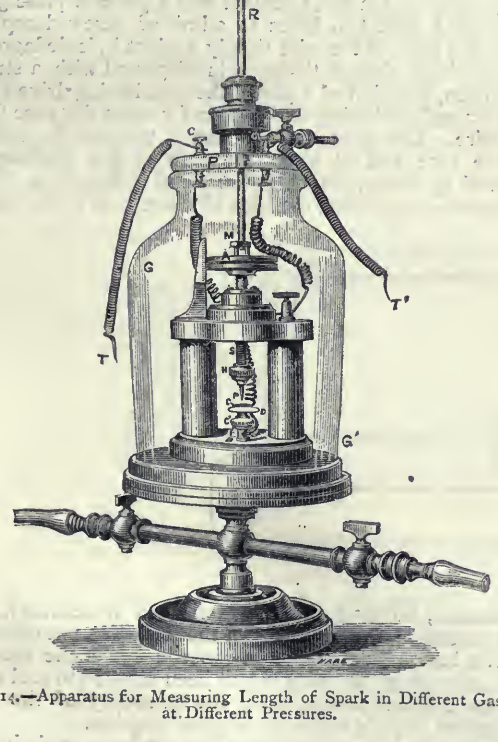

FIG. 14.—Apparatus for Measuring Length of Spark in Different Gases or at Different Pressures.

clamps *c c′* with which the terminals of the battery T T′ were connected. Through a stuffing box in the glass cover a steel rod R passed; this, below the glass, carried a crutch M, with two ebonite pins, which drop into corresponding holes made to receive them in the micrometer wheel A; the rod had on the top, outside the jar, a cross handle *h* for turning it. The distance of the terminals was easily regulated by means of this rod, as the micrometer could be read through the bell glass. Before admitting any gas into it, the bell glass was exhausted by the mercurial pump to a pressure of less than a millimetre, then filled with dry gas, and again exhausted and recharged. The following table shows the results obtained with spherical surfaces 1·5 inch in diameter and 3 inches radius.

Gas.	Length of Spark.	Ratio of Length of of Spark.		Ratio of "Electric Viscosity."	
		Referred to Air.	Referred to Hydrogen.	Referred to Air.	Referred to Hydrogen.
	Inch.				
Air	0·082	1·000	0·547	1·0000	1·828
Hydrogen	0·150	1·829	1·000	0·5467	1·000
Oxygen	0·082	1·000	0·547	1·0000	1·828
Carbonic anhydride	0·077	0·939	0·513	1·0650	1·949

The appearance of the arc was different in different gases, as will be seen in Fig. 15, where 1 represents the arc in air; this when examined with the microscope pre-

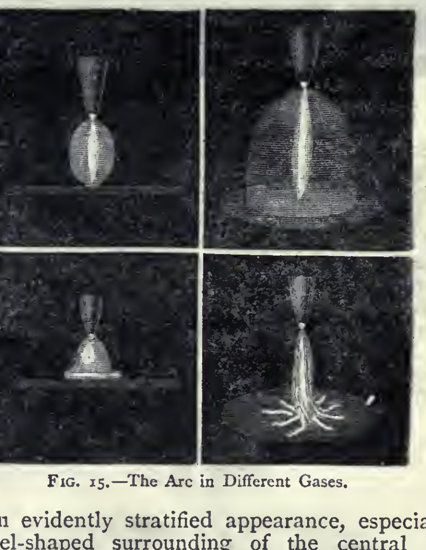

FIG. 15.—The Arc in Different Gases.

sented an evidently stratified appearance, especially in the barrel-shaped surrounding of the central bright spindle; the laminæ were extremely close and seen with very great difficulty, even with the revolving mirror of the microscope; with a moderate magnifier, a hand lens, the barrel-shaped surrounding appeared as if shaded with lines across it.

The arc in hydrogen, with the point positive, is shown in 2, Fig. 15; the central spindle was surrounded by a beautiful blue halo like a glass shade illumined by fluorescent light, and very brilliant on the disc. With four megohms resistance in the circuit, the streaming discharge from the point positive, at 0·502 inch distance, was carmine in colour. This distinctive colour is a proof that the gas in which the discharge takes place is the carrier of electrification in the streamer discharge. The appearance of the arc when the point is negative is shown in 4, Fig. 15; it moved about very rapidly and formed a star-like appearance on the positive disc; when the point was negative, before the jump of the spark, a very pale glass-shade-like halo, of a saddened olive tint extended from the point almost to the outer periphery of the disc.

The arc in nitrogen was reddish violet, and in oxygen it presented an appearance similar to that in air. The arc in carbonic anhydride is shown in 3, Fig. 15.

In the course of their experiments several curious and interesting phenomena were noticed incidentally. A slip of dry glazed note paper, when placed upon the disc of the discharger (Fig. 4), the other terminal being a point, was attracted to the disc so as to require a lateral pull amounting, in some cases, to as much as 30,000 grains, to cause it to slide over the disc: this lateral strain was reproduced when the paper was pressed against the disc by a weight of 129,690 grains. We must refer our readers to the original memoir itself for the full discussion of this phenomenon.

When the terminals were placed opposite to two gas jets emanating from the same gas pipe in metallic communication with the gas main, and consequently to earth, the flame opposed to the negative terminal is attracted, but that opposed to the positive *repelled*, as was observed to be the case with static electricity by M. Neyreneuf, at whose request the experiment was made. Fig. 16 shows the arrangement and effects observed.

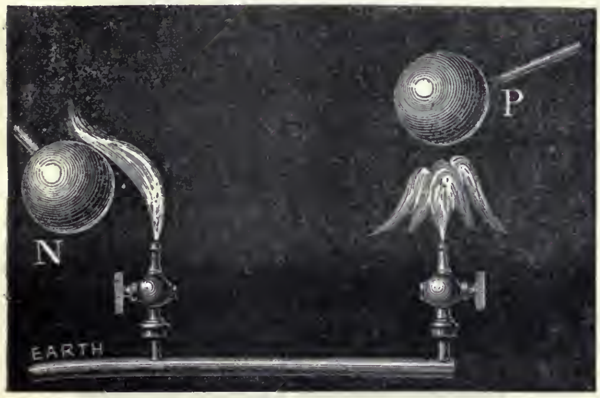

Fig. 16.—Repulsion of Gas-flame.

"When one of the terminals consisted of a very fine platinum wire 0·002 inch diameter and about 0·56 inch long, held in a holder like that used for holding needles in a mathematical instrument box, but adapted to go into the discharger, the wire took up a straight, circular, or elliptical oscillation, the glow at the point forming a continuous line of light marking its course; with the point positive the excursion was less than when negative, being with a potential of 8,040 cells, and a distance between the terminals of 0·32 inch, about 0·375 inch; with the point negative it was much more brilliant and about 0·8 inch. By interposing a resistance of 4 megohms the statical discharge took place from the extremity of the wire, frequently producing a beautiful and brilliant figure by the apparent crossing and interlacing of the bright lines of discharge from different points in the path of the oscillating wire; these occurred at such short intervals that the discharge looked like a persistent pattern of intricate engine-turning. By approaching the wire cautiously it was generally possible to cause the end of it to fuse into a minute globule, and the discharge then became much more striking. With 4 megohms resistance the static spark was longest and brightest when the wire was negative; if the wire was very straight, the oscillations took place in a cycloidal curve in a vertical plane, the discharge occurring at equal distances from the middle of the path as the minute globule at the end of the wire attained the limit of the greatest discharge from either side, so that two streaks of light were seen continuously; if the wire was slightly bent, the oscillation was conical or elliptical, and the figure produced by the discharge was then much more continuous and beautiful, because the distance from the point to the plate remained nearly constant."

Another point studied by the authors was the deflagration of wires of different metals. With their condenser of 42·8 microfarads charged with 3,240 cells, they could deflagrate 10·5 inches of platinum wire 0·0125 inch in diameter. When 2½ inches of either platinum, gold, silver, copper, iron, zinc, or aluminium wire of this size, strained across and kept in close contact with a piece of plate glass perforated with two holes to admit of screw clamps to press the ends of the wire tightly against it, is deflagrated by the above charge, the wire is dispersed with a strong explosion, like that of a pistol, the metal being driven into and strongly adhering to the glass for some distance from the wire. The greatest dispersion is towards the middle of the wire, and all along the path of the discharge is crossed by furrows in which the metal is deposited. This appearance suggested the idea of a stress at right angles to the path of the discharge which might involve a notable longitudinal contraction.

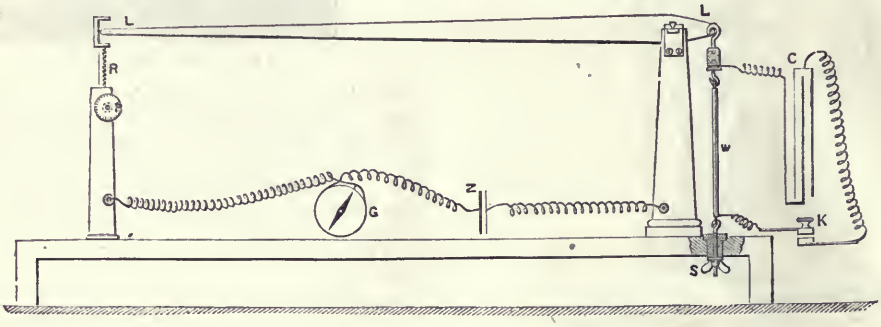

Fig. 17.

An experiment was made to test this hypothesis, but the results were entirely negative. When the key K (Fig. 17) was pressed down the accumulator C was discharged through the wire W, which was 8 inches long, and of diameters varying from 0·2 to 0·0125 inch; if now the wire had, at the moment of discharge, contracted longitudinally by $\frac{1}{13000}$ inch, the fact would have been recorded by the deflection of the galvanometer G, in consequence of the closing of the circuit of the battery Z, at the extremity of the long arm of the lever; with this apparatus, however, the contraction, if it occurred, was not detected; the extremity of the lever was not observed to rise before it descended in consequence of the elevated temperature of W; after W had been allowed to cool down to its original temperature, the extremity of the lever remained slightly below its original position.

Only a few experiments have as yet been made by the authors on the length of spark at different pressures below that of the atmosphere, but they intend to pursue this investigation with a micrometer discharger of longer range than that shown in Fig. 4.

With two spherical surfaces, each of 3 inches radius of

curvature and 1·5 inch diameter, the following results were obtained with 8,040 cells:—

Pressure.	Fraction of an atmosphere.	Length of spark.	Ratio to length at 1 atmosphere.	Ratio of length of spark to dilatation.
Millims.		Inch.		
760	$\frac{1}{1}$	0·079	1·00	$\frac{1}{1} = 1·000$
602	$\frac{1}{1·262}$	0·100	1·26	$\frac{1·26}{1·262} = 0·999$
414·7	$\frac{1}{1·833}$	0·200	2·52	$\frac{2·52}{1·833} = 1·375$
299·5	$\frac{1}{2·537}$	0·400	5·04	$\frac{5·04}{2·537} = 1·986$
141·5	$\frac{1}{5·370}$	0·800	10·08	$\frac{10·08}{5·370} = 1·876$

ERNEST QUETELET

THE death of M. Ernest Quetelet, "chef du service Astronomique" of the Observatory of Brussels, took place at Ixelles on the 6th instant, after a long and painful illness. His connection with the observatory dates from 1855, when he entered it as an assistant to his father, the late Lambert Adolphe Jacques Quetelet, who was then the director, and who died so recently as February, 1874. Ernest was born in Brussels August 7, 1825. At that time his father was busily occupied in pressing on the king and the municipality of Brussels the importance of establishing an observatory for meteorological purposes. After much discussion and many delays it was determined in 1826 to establish an astronomical observatory; Quetelet was directed to obtain instruments, to visit Paris and London, and on January 9, 1828, he received his official appointment, his title being "astronomer." The three principal astronomical instruments were set up in 1835, but the first four volumes of the *Annales* of the observatory coming down to 1845 contain only meteorological notes. The first volume (date 1834) opens with an "aperçu historique des observations de météorologie faites en Belgique jusqu'à ce jour," commencing with 1763, and shows how thoroughly the director entered into the importance of the work. The observatory in 1845 was the centre of meteorological observing stations, of which there were more than eighty.

Although Ernest, as he grew up, shared his father's interest in the various observations included under the head meteorological, and took terrestrial magnetism as a special subject for study, on joining the observatory in 1855 he was appointed to take the astronomical observations and the *Annales* record that the observations were made by him and the calculations of the reductions by M. L. Estourgies. From 1857 he has had in hand the revision of a catalogue of the variable stars, a large part of which has been published. Two years ago he issued the climatological elements of Brussels, in a series of eighteen tables, for the ten years ending 1873, and in the *Bulletin* of the Société Royale are many papers by him on magnetism.

Before entering the observatory he was in the Engineers for several years, after having passed through the École Militaire of Brussels. In 1848 he was engaged as a subaltern on the work of the fortifications of Antwerp. It was while still in the Engineers he communicated his first paper to the Academy, "Recherches sur les Médianes" (October 9, 1859), which was printed in the *Mémoirs Couronnés*. In 1856, shortly after joining the Observatory, he wrote a paper on the magnetism of the earth in North Germany and Holland, and in 1859, "On the Magnetic Declination at Brussels."

The Observatory has all through its existence had to struggle against difficulties; one of the latest recommendations of the Commission on it was to effect the following improvements:—

"To complete the magnetic system of the Observatory by the acquisition of self-registering instruments, to organise the International Meteorological Service, to obtain an equatorial of large dimensions with the accessories necessary to the spectroscopic investigation of the heavens, and to increase the number and improve the position of the observer."

During many years M. Quetelet has often been appointed referee to the printing of papers in the *Mémoires* of the Académie Royale, and has been himself a frequent contributor.

GEOGRAPHICAL NOTES

IN the Geographical Section of the French Association some papers of interest were read. Dr. Carret read a curious paper on the Distribution of Antipodes, in which the author indulged in some rather fanciful theorising. Gen. Ricci spoke on the geodetic work carried on by the Italian Government, which is energetically completing the triangulation of Italy, connecting it with the rest of Europe on the one side and Africa on the other. Gen. Ricci also spoke of the regular tidal observations carried on at various stations on the coast of Italy, mainly with a view of getting a true level for geodetic purposes. M. H. Duveyrier read an elaborate paper on the remaining problems in African geography, in which he divided unknown Africa into seven great regions: (1) The Sahara and the Libyan Desert; (2) The country between the Joliba and the Guinea Coast; (3) The upper courses of the Binue and Shari; (4) The region behind Cape Guardafui; (5) The equatorial chain of lofty mountains; (6) The completion of the basins of the Nile, Congo, and Ogove; (7) The basin of the Cunene. Altogether more than 11,000,000 square kilometres remain unexplored, more than one-third of the whole surface of Africa. At the mean rate of discovery since the beginning of the century, this might be covered in about forty-eight years, though the ratio is now so increased that it ought to be done in much less time. A paper by M. Maunoir recounted the services done to geography by France since 1800, and when all put together with the eloquence of a Frenchman, they seem formidable.

NEWS from Capt. Tyson's Arctic expedition in the *Florence* has been brought to Washington by the schooner *Helen*, which wintered in the same bay on the coast of Cumberland. Meteorological observations were taken most accurately during winter by Mr. Sherman, the physicist of the expedition. Unfortunately the naturalist inflicted on himself a wound when on duty, and was disabled for the greater part of the winter. Capt. Tyson went to Disco to recruit natives, collect goods, and purchase dogs. He fulfilled his duty with his wonted activity and success. But when everything was ready he learned by a message sent from Washington that the preparations were useless, the American Congress having taken its vacation without deliberating upon the report so carefully drawn by the Marine Committee. The brave and accomplished commander of the *Florence* is now on his way to Washington, where he is expected daily. We are informed that a demonstration will be made against this piece of Parliamentary negligence. This preliminary expedition was entirely fitted out at the expense of Capt. Howgate and his friends.

NEWS has arrived that the Bremen steamer *Neptune*, Capt. Rasmussen, which left for the Ob, in Siberia, on July 16, reached Hammerfest on the 6th instant with a full cargo of Siberian wheat. The *Neptune* was laden with all sorts of mercantile goods. She entered the Nadym on August 13, and had no ice difficulties on the voyage out. Perhaps in future, when the

navigation of the estuary of the Ob is better known, the voyage may be made in even a shorter time. Indeed if depôts were established at suitable points on the north Norwegian coast, it might be possible for a ship to make two journeys to Siberia in one summer. Probably the Ob is the most important of the Siberian rivers so far as commerce is concerned. Trade on the Ob is already considerably developed, the river being navigated by over thirty steamers. The region around the river is the most productive and most thickly inhabited in Siberia.

IN an article in the September number of Petermann's *Mittheilungen*, on the chief branches of the Russians, much interesting information is given on the characteristics and distribution of the Great, Little, and White Russians, illustrated by a carefully constructed map. In the same number Dr. Junker, in a letter to Dr. G. Schweinfurth, describes his travels in the south-west part of the Nile Region in January-October, 1877, adding considerably to our knowledge of the region, and making several corrections on existing maps. Lieut. Weyprecht describes the results of his observations in 1871-4, on the temperature and depth of the sea to the east of Spitzbergen. The sea, he finds, is comparatively shallow, seldom exceeding 400 metres.

WE have received a handsome atlas of the State of New Hampshire (U.S.), containing, besides a series of beautifully-executed maps of the state and of its counties,—meteorological, geological, agricultural, and arboricultural,—a vast amount of well-arranged information on its topography, geography, river systems, climatology, railroads, educational institutions, agricultural and botanical productions, mechanical and manufacturing interests, &c. The work is edited by Mr. H. F. Walling, C.E., and Prof. C. H. Hitchcock, and is published by Comstock and Clive, New York. The work is creditable both to the editors and publishers. The long list of "patrons" of the atlas appended—mostly people in business—speaks well for the intelligence of the inhabitants of New Hampshire.

IN a letter to Sir Samuel Baker from a gentleman in the Khedive's service, the latter describes a successful journey which had been made with some Indian elephants in the White Nile region, proving that this powerful and useful animal may be utilised advantageously in African travel and exploration.

OUR ASTRONOMICAL COLUMN

THE INTRA-MERCURIAL PLANET.—In addition to the letter addressed to the Astronomer-Royal by Prof. James Watson, after revising his first position of the object near θ Cancri, more carefully at Ann Arbor, similar communications have been made to M. Fizeau (*Comptes Rendus*, May 2), Prof. Förster (*Circular zum Berliner Astronomischen Jahrbuch*, No. 98), and to Prof. Peters (*Astronomische Nachrichten*, No. 2,217). The definite position is in R.A. 8h. 27m. 24s., Decl. + 18° 16′ for July 29, at 5h. 16m. 37s. Washington M.T., or 10h. 24m. 49s. M.T. at Greenwich, which position Prof. Watson considers to be trustworthy within five minutes of arc, with a greater probable error in the declination than in the right ascension. The other points named by the discoverer, upon which stress is to be laid, are the fact of the star θ Cancri being also observed, the appearance of a sensible disk with a power of 45 on a 4½-inch refractor, its ruddy colour and much greater brightness than that of the neighbouring star. There has never been a suspicion of a variable star in this vicinity, nor can the appearance of a disc be so explained. Prof. Watson seems to have satisfied himself that the object was not a comet; indeed, such a body would hardly appear round and well-defined with the sun totally eclipsed. In the case of the comet of March 1847, which was observed in full daylight, at a similar distance from the sun to that of Prof. Watson's object, two short tails were visible though the head was circular, and the great comet of February, 1843, also exhibited a bifid tail, which was bright and distinct to the naked eye. Mr. Hartnup, who observed the comet of Klinkerfues, 1853, in broad daylight, described it as circular, well-defined, and without tail, but the case is hardly analogous to that of a comet viewed while the sun is wholly hidden.

[Since the above was in type, the full details of Prof. Watson's observations and reductions have been received.]

THE VARIABLE NEBULA IN TAURUS (HIND, 1852).—In the diagram attached to M. Tempel's remarks upon this object in *Astron. Nach.*, No. 2,212, a distinction is made between the position given in No. 839 of the same periodical and that assigned with reference to the neighbouring variable star T Tauri. To prevent misconception on this point it may be well to remark that, on the first night the nebula was perceived with Mr. Bishop's seven-inch equatorial—October 11, 1852—it preceded the variable star 1s.·2, and was south of it 0′·7, as stated in the *Astron. Nach*, and that at no subsequent time when the nebula was observed with the same instrument was any difference of position noticed: it appeared to nearly touch the star on the S.P. side. No. 1 on M. Tempel's diagram should be therefore erased. In a note in his Supplementary Catalogue Mr. Dreyer states that he found no appearance of nebulosity near the well-known variable; nor did Dr. Copeland, observing with the large refractor at Lord Lindsay's Observatory; nor M. Tempel, with a fine Amici of 11-in. aperture, at Arcetri. On the other hand, M. Otto Struve still found traces of nebulosity with the Pulkova instrument, which he "believes is certainly the variable nebula itself, only in altered brightness and spread over a larger space;" and he adds, "some traces of nebulosity are still to be seen exactly on the spot where Hind and d'Arrest placed the variable nebula." The accurate position of T Tauri has yet to be determined by meridional observation. Argelander re-observed Bessel's star of the ninth magnitude, which precedes it 16·5s., about 4′ south.

THE LATE DR. E. VON ASTEN.—By the early death of Dr. von Asten astronomy has lost a most able worker in a branch which has numbered of late years fewer distinguished names than formerly. He was one of Argelander's pupils and intended to apply himself to observations, but, we believe, through a serious accident, he was incapacitated for active occupation, and his desire to devote his attention to astronomy could only be gratified by obtaining employment in calculation. This he was so fortunate as to effect through the director of the Imperial Observatory at Pulkova, M. Otto Struve, who engaged him as one of the staff of computers. In this position Dr. von Asten had for some time carried on a rigorous investigation on the motions of Encke's comet, one of the most interesting results of which has been to prove that while in some revolutions an acceleration similar to that attributed by Encke to the existence of a resisting medium has made itself evident; in others the motion of the comet could be precisely followed without such hypothesis, and hence a different cause might be found for the cases of acceleration. Dr. von Asten previous to his connection with Pulkova, minutely discussed the whole of the observations of the great comet of Donati (1858 vi.), arriving at the conclusion that at the time it was visible it was moving in an elliptical orbit with a period of nearly 1,900 years.

NOTES

THE Association of German Naturalists and Physicians commenced its sittings at Cassel on Wednesday last week, and judging from the numbers of the *Tageblatt* and of the Cassel papers that have been sent us, the meeting has been quite as

successful as usual. Every provision had been made by the local authorities for the reception of the Association, and while abundance of serious work has been done, a fair proportion of the time has been given to enjoyment. Among the arrangements, for example, are performances of "Faust," "Midsummer's Night's Dream," "Comedy of Errors," "Tannhäuser," and other classical pieces in the theatre, and among the excursions is one to the Paris Exhibition. The president, Dr. Stilling, in his opening address, traced the history of the scientific life of Cassel, showing that much good work had been done there, and that the names of not a few eminent men of science have been connected with the city. The title of Prof. Oscar Schmidt's lecture seems sensational enough—"Darwinism and Social Democracy,"—but his treatment of it seems to have been quiet enough; he aimed at showing that Darwinism instead of being a leveller, showed the tendency to be everywhere to heterogeneity. Prof. Hueter, in his lecture on the Physician in Relation to Research and Natural Science advocated a longer curriculum for medical students and a more thorough training in science and in the experimental method. The numerous sections were busy enough, and many good papers were read, but any further account of the proceedings we reserve till we have received a complete set of the *Tageblatt.*

IN the terrible panic which has seized the Southern States under the epidemic of yellow fever, we are glad to see that science has been pressed into service and stuck bravely to her post. Every one who can is flying for life, but it has been deemed advisable to retain the sergeants of the United States Signal Service at their posts in order to keep up for the use of the medical men regular observations of temperature, humidity, and other atmospheric phenomena which may have any influence in the spread of the disease. One of these officers died at his post and two others had been struck down, probably also fatally, as we learn from the New York *Tribune.* It is encouraging to see that the United States authorities have kept their heads clear enough to perceive that the services of science are indispensable to "the healing of the nations."

M. BISCHOFSHEIM, the well-known Parisian banker, has sent a sum of 10,000 francs to the French Bureau Central Météorologique to help in the construction of the intended Mont Ventoux Observatory. We may remind our readers that he, at the suggestion of his friend M. Leverrier, helped in the same manner the construction of the Puy-de-Dôme and Pic-du-Midi establishment. M. Bischofsheim has also agreed to pay M. Eichens 1,000*l.* to complete within a year the construction of the great refractor begun in Leverrier's time in 1870.

THE fitting up of the Lyons Observatory is progressing favourably; the inauguration will take place in a few weeks.

WE noticed with regret a few weeks ago that a tax had been imposed on the French communes to entitle them to receive the daily meteorological telegrams of the Bureau Central. A new delay has been granted for the subscription, and we are happy to state that a large number of rural parishes, fully appreciating the importance of the service rendered by the telegraphic warnings, have already agreed to pay the yearly charge, which has been reduced to forty francs.

M. COCHERY, the director of the French postal telegraph, is now in London studying the working of the English system and hopes to introduce into the French service a number of improvements which the large traffic and progressive character of the English service has brought into use.

THE meeting of the Iron and Steel Institute opened at Paris on Monday, with a presidential address by Dr. C. W. Siemens, who showed how comparatively well provided France is with institutions for scientific education, and referred briefly to the work carried on at some of the great industrial centres. We have already given a list of the papers to be read, all of them of more or less technical bearing.

THE fourth Congress of Orientalists commenced its sittings this year at Florence on the 12th inst. The chief nationalities have been well represented, and the reception by Florence and by Prince Amadeo has been hearty. One attractive feature is an extensive exhibition of objects connected with the subjects with which the Congress deals.

THE Fourth Annual Conference of the Cryptogamic Society of Scotland, will be held at Edinburgh on October 9, 10, and 11. The programme includes excursions, a dinner, and an exhibition of fungi. The meeting-place is the Botanic Gardens of Edinburgh, the president is Prof. Balfour, and the secretary Dr. Buchanan White, Perth.

AN agricultural exhibition took place at Lockwitz, near Dresden, on September 5–7. It formed part of the general meeting of the Saxon Agricultural Society which enjoys the special patronage of the King of Saxony.

THE Congress for 1878 of the German Viticultural Society was held at Würzburg on September 15–19.

GREAT activity continues to be manifest in Vesuvius, and volumes of lava are projected to a height of 100 yards above the new crater, accompanied by loud explosions. However, no flames are yet visible.

SINCE M. du Moncel presented the Edison phonograph to the Academy of Sciences electrical inventions of every description are sent to him for presentation. A large number of these deserve notice, and no sitting passes without M. du Moncel speaking on two or three different inventions. This state of things has created some anxiety amongst members unable to understand electrical matters. On Monday week one of them proposed to the president that M. du Moncel be obliged to execute all the experiments he was describing before the Academy, in order to prove whether they were sound. M. du Moncel replied that he was himself verifying them with much care, but that a number could not be executed before the learned assembly, as two different stations, situated at a great distance, were required; and he reminded them that, when he brought the phonograph before the Academy, he had taken the precaution to procure an able operator for the working of it. The point of the reply is that a certain number of the members said that the phonograph was exhibited by a ventriloquist. M. Fizeau, who was in the chair, called the assembly to a vote, and the discussion ended. It was not recorded in the *Comptes Rendus.*

AT the meeting of the Botanical and Horticultural Congress in Paris, the following were among the most interesting communications and discussions:—On the influence of the age of seeds on the plants raised from them. Prof. Baillon found that Prof. Cazzuole's view, that the newer the seeds of *Cucurbitaceæ* the larger the proportion of male flowers, and *vice versâ*, was not confirmed by his own experiments, in which he had sown melon-seeds dating from 1870, and for comparison last year's seeds.—On double flowers. Prof. Morren, in support of his well-known theory of the incompatibility of truly variegated leaves and double flowers, pointed out that in the camellia and *Kerria japonica* normal flowers are only known to occur on variegated stocks. In a Hibiscus, which unites these peculiarities, the flower-buds fall without opening; in a variegated and double wallflower, many of the branches revert and are quite green.—Descriptions were given of the chief botanical laboratories in St. Petersburg, Amsterdam, Florence, and Paris.

In the last city there are no less than four in active work, viz., those of the Sorbonne, École de Médicine, École de Pharmacie, and Muséum (Jardin des Plantes) respectively, besides one for experimental physiology at Vincennes.—On the question of gymnospermy. Prof. Arcangeli's anatomical researches had led him to conclude that the coat of the ovule in Gymnosperms was sometimes carpellary in origin, but not always. Unfortunately no discussion followed.—M. Sirodot gave an abstract of his researches on *Batrachospermum*, which he shows is the sexual form of *Chantransia*.—M. Borodin gave an account of the variations in the excretion of CO_2 in leaves of different ages. —M. Millardet found the lesions from phylloxera differ according as the part attacked is the young rootlet or an older part. In the latter case a septum of cork is often formed to preserve the parts that remain healthy. Unfortunately the question of the "Hortus europæus" was hardly discussed, but suggestions were made for the compilation of a new "Steudel." Besides the excursion to Segrez, a large number of members were conducted, on the 22nd, all over the remarkable irrigation works at Genevilliers (where a fourth of the sewage of the city of Paris is utilised), by M. Durand-Claie, Engineer to the Works, and M. H. Vilmorin, Secretary to the Commission d'Etudes. Afterwards many of the foreign members breakfasted with M. E. Cosson, and visited his splendid herbarium, and in the evening was held the banquet of the Congress. On the 23rd a large party visited the gardens of the Jardin des Plantes with Prof. Decaisne, and the herbarium with Prof. Bureau. The final session of the Congress was held at Versailles on the 25th, after which the members visited the show of the Horticultural Society of the town, at whose annual banquet the foreign members were entertained in the evening.

A VERY useful paper "On Lightning Conductors and Accidents by Lightning" was read at the British Association meeting by Richard Anderson, F.C.S. So slow has been the "march of progress" in the application of one of the greatest scientific discoveries of modern times to the uses of daily life, that even now, after the lapse of more than a century, the employment of lightning conductors, simple as they are, and as inexpensive as simple, is far from being general, still less universal. At least one-half, and perhaps two-thirds, of all the public buildings, including the churches and chapels, of Great Britain and Ireland, are without protection against lightning. As to private houses, it is safe to assert that not five out of every hundred have lightning conductors. It is well known that the amount of property destroyed annually by lightning is very great, though it is naturally impossible to form any estimate of it. The terrible losses, both of property and human lives, still occasioned by lightning, are the more lamentable, as they are in nearly all cases the result of the grossest negligence. The negligence is three-fold—namely, first, in not providing any lightning conductors at all; secondly, in not placing them in the right position, or in sufficient number to cover a given area; and, thirdly, in not having them regularly tested, so as to ascertain their constant efficiency. Even some of the first cathedrals of England, such as Peterborough, have no lightning conductors whatever, while others, supplied with them, are insufficiently protected, as is apparent to any competent observer. Mr. Anderson gives striking examples of the absence of lightning conductors, and of the disastrous effects of their being badly placed. The third cause of neglect is by no means the least. Mr. Anderson justly argues that lightning conductors ought to be at regular intervals, at least once a year, carefully inspected, and their efficiency tested by a galvanometer. The absolute neglect of this precaution which is now prevailing is no doubt the cause of a vast number of casualties by lightning, inflicted upon buildings nominally protected by conductors. Utter neglect of the conductor, when once it has been put in its place, is the commonest thing, and indeed the rule, as regards private dwellings; and, we fear, there is little difference in this respect as to most public buildings, churches, and chapels. In fact, it is the old case of a matter of however great consequence, yet being utterly disregarded as "nobody's business." Between three and four thousand pounds were spent in protecting the Houses of Parliament by lightning conductors at the time of their erection, some twenty years ago. Since that time, as far as Mr. Anderson can learn, after minute investigation, they have never been tested, and there is no guarantee whatever that a discharge of lightning may not at any time fall upon the Queen's throne, the Lord Chancellor's woolsack, or the Speaker's chair. A French writer pithily expresses the results that follow from a lightning conductor over a house not having a proper "earth connection," by saying it is lightning guided to the owner's iron bedstead. Mr. Anderson then gives several useful practical instructions as to what ought to be done to amend the present unsatisfactory state of matters, which well deserve attention. As the clock in churches and other public buildings is methodically inspected by the clockmaker, so ought every lightning conductor to be as systematically examined by an electrician or other competent person. Already such a system of inspection and testing of conductors exists in Paris and several other French towns. Shall we say, once again, "They manage these things better in France?"

THE long-expected report of the United States Entomological Commission, appointed to investigate the ravages of the locust, has been published as one of the series of Dr. Hayden's survey, and constitutes a very important addition to the scientific and practical literature on this subject. Although it has been several years since there has been any serious damage caused by the Rocky Mountain locust, their enormous destructiveness, when they do occur in abundance, is such as seriously to threaten the prosperity of the States in which their ravages are prosecuted. The present report professes to be for 1877, and posts the subject up to that date, being a stout volume of nearly 800 pages, and is accompanied by excellent wood-cuts and engravings, representing the insect and its winged and other enemies in all stages of development and condition. In addition to the descriptions of the species and its general natural history, various remedies and devices for its destruction are communicated; also notes on the influence of prairie fires on the increase of the locust, the influence of the weather on the species, the effects which generally follow severe locust injury, and the uses to which locusts may be put. There are also chapters on the ravages of other species of locusts in the United States and on the ravages of locusts in other countries. Congress at the last session provided for the continuation of the inquiry for the present year under the same commission.

MR. W. H. SHRUBSOLE informs us that an imperfect tooth recently found in the London clay at Warden, in the Isle of Sheppey, has been submitted by him to Prof. Owen, who says of the specimen that "it suffices to determine both the mammalian and ungulate nature of the animal it belonged to; that it comes nearest to the kind of *Palæotherium* figured in 'British Fossil Mammals,' p. 322, Fig. 116, but is too incomplete to show the genus or species." Mr. Shrubsole adds that there is no record of any mammalian remains having been found in Sheppey before.

MESSRS. CHURCHILL will publish, early in November, a work on the poisonous snakes of India, by Dr. Ewart, illustrated with coloured plates reduced from Sir Joseph Fayrer's large folio work.

MESSRS. TEGG AND CO., Pancras Lane, will shortly publish "Berkeley's Principles of Human Knowledge," with Introduc-

tion and Copious Explanations, by Collyns Simon, LL.D., author of "The Nature and Elements of the External World," and Proposer of the Berkeleian Prizes in 1848 and 1850.

A NEW book on Ferns has just made its appearance at Salem, Massachusetts, under the title of "Ferns in their Homes and Ours." Its author is Mr. J. Robinson, Professor of Botany, Massachusetts Horticultural Society, and the book forms one of a series called the "American Natural History Series." It has been put together especially for the use of persons residing in the United States, but the author has nevertheless made himself thoroughly acquainted with the works of European pteridologists and pays a high tribute to those of our own country, notably the more recent works of the veteran John Smith. Though the book commences with a consideration of the life-history of a fern, classification, distribution, and nomenclature, it is for its practical part, dealing with the selection and cultivation of these favourite plants in living, that the book will be most valued.

NEWS from Denmark states that the last pillar of the first fixed bridge across the Lim Fjord has now been finished; the new bridge will connect Aalborg on the south side of the fjord, with Norresundby on the north, and it is hoped that it will be opened for traffic during the autumn. Our readers will remember that the Lim Fjord is an arm of the sea stretching right across the Danish continent from east to west.

SOME interesting excavations have been recently made at the "Limburg," a large ruin near Dürkheim in the Bavarian Palatinate, at the instigation of the German Anthropological Society. During 1877 prehistoric remains had been found at this spot, and the work being continued this year, numbers of urns, human and animal bones were discovered, all undoubtedly of prehistoric origin. The most interesting part of the discovery is the laying bare of a cremation ground.

A PAPER on "The Salt Lakes, Deserts, and Salt Districts of Asia," by Mr. Thomas Ward, read before the Liverpool Literary and Philosophical Society has been published separately, with a map. The author endeavours to illustrate from what is known to be going on in the formation of salt at the present time, the way in which salt was formed in past ages.

THE Rev. Thomas Powell, of Upolu, Samoa, writes us that in vol. xv. of NATURE, p. 503, in our report of the Linnean Society, his paper on "Poisoned Spears and Arrows" is represented as having reference to *Samoa*. Mr. Powell sends us a corrected copy of the paper from which we see that the paper has reference to the New Hebrides. The Samoans, Mr. Powell states, have no such custom as the use of poisoned weapons of any kind. They formerly made use of the bow and arrow, not, however, for purposes of war, but of sport only. The introduction of fowling-pieces has abolished the use of the bow. Another error, Mr. Powell writes, into which we have been led is the statement that *Callophyllum inophyllum* was among the trees whose milky juice was used as a poison. This is not Mr. Powell's statement. His informant said that the *Toto* resembled that tree in general appearance. The *C. inophyllum* is a valuable timber tree in common use. Its flowers and fruit are used in Samoa as a perfume. From its fruit an oil is extracted in Fiji, which is useful as a liniment in rheumatism.

THE additions to the Zoological Society's Gardens during the past week include a Banded Ichneumon (*Herpestes fasciatus*) from West Africa, presented by Mr. F. T. Blackley; two Vinaceous Turtledoves (*Turtur vinaceus*) from West Africa, a Greek Land Tortoise (*Testudo græca*), European, presented by Miss Harris; a Common Adder (*Vipera berus*), European, presented by the Viscount Mandeville; a Spotted Turtledove (*Turtur auritus*), bred in the Gardens.

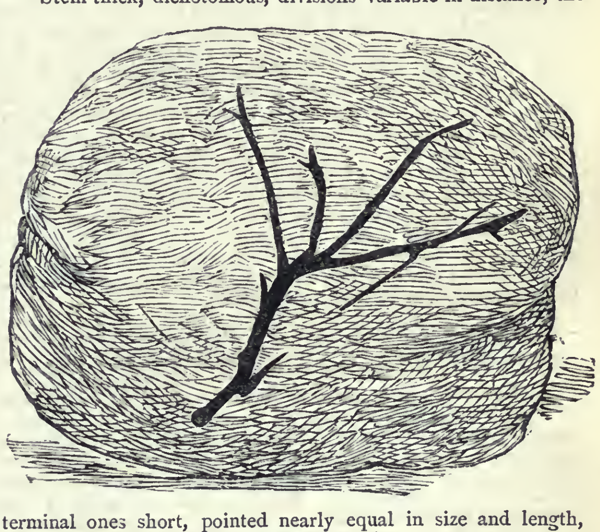
A FOSSIL PLANT[1]

MANY years ago the late Sir William Logan drew attention to the occurrence of fossil plants in the Devonian strata of Canada, and Prof. J. W. Dawson, F.R.S., in the *Quarterly Journal* of the Geological Society, in vols. xv. and xviii., described and figured some of these specimens. Amongst them was a plant which he designated *Psilophytum*. Dr. S. S. Scoville has since discovered the remains of plants in the lower silurians at Longstreet Creek, near Lebanon, Ohio, which Prof. Newberry considered as the casts of some large fucoids or marine plants. Count Saporta has found the branch of a fern in the silurian schists or slates of Angers, France. Prof. Leo Lesquereux, to whom we owe so much for his labours in investigating the fossil plants of the United States, in a paper read before the American Philosophical Society, October 10, 1877, has described and figured a plant from the lower Heldeberg sandstone, Michigan, under the name of *Psilophytum cornutum*.

In a paper read by myself before this society on December 26, 1876, I stated that after some years' search I had not been able to find the *Palæochorda major* mentioned by Professors Harkness and Nicholson as occurring in the Manx schists in such a state of preservation as to be certain of its true nature, but I had a fucoid in my possession found by Mr. Grindlay in the drift near Laxey.

As Mr. Lesquereux's specimen so much resembles the one found at Laxey I shall give his description at length.

"Stem thick, dichotomous, divisions variable in distance, the



terminal ones short, pointed nearly equal in size and length, surface slightly rugose and irregularly striate.

"The branches in the lower part are thick comparatively to their length, three or four millimetres, irregularly striate when decorticated, or merely punctuate upon the thin bark with small projecting dots resembling the basilar remains of scales or small decayed leaves; lateral branches short, narrowed to a sharp point; the upper or terminal ones about equal in length, appearing like a pair of pointed horns."

The species is only comparable to some of the fragments not specified but figured by Prof. J. W. Dawson (Geol. Survey of Canada, Fossil Plants of the Devonian and upper silurian formations, Figs. 243, 244). The author remarks "that these fragments are probably originating in the upper silurian of Gaspé; that as they are found in the lower part of the limestone which underlies the Devonian Gaspé sandstone and become more abundant in the upper beds, this suffices to indicate the existence of the neighbouring land, probably composed of silurian rocks and supporting vegetation."

From the preservation of its branches even to the smallest subdivisions, the specimens here represent part of a plant embedded in the place of its growth. The matrice is a piece of very hard calcareous shale seven to eight millimetres thick, bearing on one side irregular undulations like ripple marks, without any trace of organic remains, and on the other the fragments of plants as figured here. The branch in (*a*) represents a different species,

[1] "Notice of a Fossil Plant found at Laxey, in the Isle of Man," by E. W. Binney, F.R.S., F.G.S., President, paper read at the Literary and Philosophical Society, Manchester.

and indeed a marine or rather a brackish plant, closely related to the species of the present genus *Chorda*, Stack. This fragment seems to have been mixed in the tide pools with fresh water or land plants growing there. For another thick specimen of the same locality and compound bears a profusion of marine mollusks, and has only branches of this as yet undescribed marine species, *Calamophycus septus*.

Habitat lower heldeberg sandstone, Michigan, discovered and communicated by Dr. Carl Rominger (State Geologist).

On comparing my Manx specimen, which was found on the surface in a field at Laxey with that figured and described by Prof. Lesquereux, it agrees with the latter in every respect, except that striæ and scales are not observable on the stem. The stem is thick, dichotomous; divisions variable in distance, the terminal ones short, pointed nearly equal in size and length, surface nearly smooth. The branches in the lower part are thick comparatively to their length. The surface of the stem appears to be smooth and affords no evidence of striæ or scales.

The woodcut on the preceding page represents the specimen a little over the natural size.

The stone in which the plant is embedded is a fine-grained grit of a grey colour, and the specimen itself is of a yellow tint as if coloured by oxide of iron; it runs nearly at right angles to the bedding of the stone, and appears as if standing in the same position as it had grown. The stone is a rolled one but it is evidently from the Manx schists found in the vicinity. These, according to Profs. Harkness and Nicholson, are of the age of the Skiddaw slates, but the rock in which the fossil occurs may be of older date, as some of the lower portions of the series have not yet been clearly determined; so here we have evidence of a plant in the lowest part of the silurian formation, or even lower. By diligent search the rock in which the specimen occurs may probably be found *in situ* in the upper part of the Laxey valley. The great resemblance, if not the identity, of the Manx with the American specimen is very remarkable, and shows the similarity of conditions then prevailing in distant parts of the globe. The specimen might have been called *Psilophytum cornutum*, if any marking on the surface of the stem had been observed, but as these appear to be absent it is proposed to call it *Psilophytum monense*. As to the nature of the water in which it grew there is no evidence from organic remains, but its characters resemble those of a fucoid more than a land plant.

THE FIGURE AND SIZE OF THE EARTH[1]

THE portion of the earth's surface bounded by the horizon which one is able to take in at one view, is but seldom a regular plane; more generally heights and depressions, mountains and valleys, alternate with each other so irregularly, that at first nothing seems farther from reality than the idea of a regular form of the earth's surface. But the more our point of view overtops the mountains which lie within the horizon, the further obviously will our range of view extend, and all the mountains and valleys which give so irregular a form to the horizon of the plain will, under this condition, become imperceptible and unimportant. Indeed, one can easily conceive that if the eye were able to comprehend at one time a much greater portion of the surface, the irregularities of the plain caused by the mountains and valleys would appear exceedingly small in comparison with the extent of surface. But such considerations must also have occurred to the ancients; for the earliest conception among the Greeks of the form of the earth's surface was that of a flat disc surrounded by the river Okeanos, into which the sun plunged nightly. The first advance was made by Thales, who said the earth must have a point of support, and imagined it was borne by the water. Anaximenes supposed that a strong dense atmosphere supported the earth. Quite another idea prevailed in India, where the earth was believed to be borne on the back of an elephant. More correct views of the figure of the earth prevailed at an earlier period in other parts of the East, in Egypt and a part of Asia. The Egyptians and Chaldeans taught at the earliest period the spherical form of the earth, and Pythagoras appears to have adopted this idea from them.

This difference of conception need not, however, be wondered at when we remember that the Greeks seldom undertook long journeys, and knew of the lands outside Greece only from fabulous narratives. It was otherwise with the people of the East, who, through their frequent and extensive travels, learned at an early period to know the positions of the stars as guides, and attained to a more correct conception of the size and form of the earth. The Chaldæans already knew the circumference of the earth so nearly that they said a good walker would take three years to walk round it.

[1] From a series of papers in *Die Natur*, by Karl Maria Friederici.

Eudoxus was the first in Greece to recognise a symmetrical curvature of the earth's surface. He had noticed on long journeys that stars which at their greatest height (culmination) stood near the horizon gradually diminished in altitude, and finally disappeared; but on his return to those regions they again gradually became visible and assumed their previous altitudes. The circumstance that these altitudes of the stars changed regularly in proportion to the length of way travelled, led him to the conclusion of a regular curvature of the earth's surface. This conclusion being accepted, a simple method was indicated for measuring the circumference of the terrestrial sphere. For suppose a star reaches at a place, A, at its maximum a height of seven degrees above the horizon, if the observer move to another place, B, lying to the north, but in the same geographical longitude as A, and measure again the highest altitude of the same star, say six degrees; then the distance of the place A from B is equal to the 360th part of the whole circumference of the earth. Let the distance between A and B be now measured, and it will be found to be sixty-nine English miles; thus the entire circumference of the earth would be $69 \times 360 =$ about 25,000 miles.

Aristotle inferred, from physical and especially hydrostatic considerations, that the earth was spherical, since, he said, the water, which formed the larger part of the upper stratum of the earth, sought, by virtue of its weight and the mobility of its molecules, to approach as near as possible to the centre of the earth, it sought to assume the lowest position, and could never be in equilibrium until all parts of its surface were equidistant from the centre of the earth, *i.e.*, formed a globular surface. This inference, near as it comes to the truth, was yet in Aristotle's time only an unproved hypothesis; the existence of a centre exerting attraction in all directions was first recognised as probable at a much later period, Newton being the first to publish the conception.

The theory according to which the earth is a spherical body, was more and more generally accepted, and was put beyond doubt when the first circumnavigation by the Portuguese Magellan (1519) became known, an example followed, at short intervals, by almost all European nations. Thus the idea so generally accepted at a very early period that the figure of the earth must be spherical, was again revived about the end of the seventeenth century. The desire to ascertain, according to the above-described methods the circumference of this circle was also cherished by the ancients, and we have accounts of measurements taken for this purpose in the earliest times, of the most important of which we give some account.

The first determination known to us of the size of the earth was made by Eratosthenes in Alexandria in the third century before Christ. He observed at the solstice (the time of its greatest northern declination) in Alexandria, the greatest altitude of the sun above the horizon, and it was known that at that time the sun stood when at its greatest altitude, in the zenith at Syene (from which we may conclude that it could be seen in a deep well). Now since the altitude of the sun above the horizon is always equal to 90° minus its distance from the zenith, he thus required only to subtract the measured height from 90°, and thus found the distance from the zenith to be the fiftieth part of the whole circumference, or 7° 12′. According to this process the distance of the two places was regarded as a fiftieth part of the earth's circumference; and as that distance, according to the accounts of travellers, was 5,000 stadia, the whole circumference of the earth was equal to 250,000 stadia. Eratosthenes altered the result to 252,000 stadia, taking for the length of a degree, 700 stadia. Without considering the great inaccuracy of his altitude measurements, there are yet too many other formidable sources of error in this estimate of the earth's circumference, to allow it any claim to much accuracy. First there was the taking for granted that both places lay on the same meridian, which was not the case, since Syene lay three degrees east from Alexandria; and second, the distance of the two places reckoned at 5,000 stadia was too great.

A second investigation was made by Posidonius in the first century before Christ, but his result was still more erroneous than that of Eratosthenes. He observed the height of one of the brightest stars (Canopus in Argo) above the horizon. It reaches, at the time of its culmination at Alexandria, an altitude equal to the forty-eighth part of the circumference, while in Rhodes it was

visible just on the horizon. Hence it followed from a calculation similar to the above that Rhodes lay about $7\frac{1}{2}°$ farther north than Alexandria, and taking the distance of the two places to be 5,000 stadia, he reckoned the earth's circumference at 240,000 stadia. Here also we find the assumption that the two places lay on the same meridian, nearly $1\frac{1}{2}°$ wrong. But the chief source of error in this observation lay in ignoring the refraction of the atmosphere, which is subject to very great differences near the horizon, and makes the stars not only appear at greater altitudes than they actually have, but disturbs the places of the lower stars much more considerably than those of the upper. But we are not now in a position to be able to discover satisfactorily the extent of these sources of error in the results of Eratosthenes and Posidonius, since the stadium was of uncertain length, and we do not know in what relation it stood to our modern measures.

These are the only results worthy of notice that have reached us from these times, for then commenced the decay of science in the east, and it was only at a much later period that it flourished for a short time among the Arabs. The Kalif Al Maimon had obtained from the Greeks the writings of their philosophers, and turning his attention chiefly to mathematics and astronomy, he was incited to undertake an investigation into the mathematical figure of the earth. He formed the resolution of undertaking the measurement of a new degree, and collected for this purpose a great number of mathematicians. These selected an extensive and level tract of land, the Sinjar Desert, and made their measurements from one point, some going north, others south. The result was that the one party found a degree of the meridian to measure 56 Arabic miles, and the other $56\frac{2}{3}$. Al Maimon had the operation repeated in order to obtain a better result, but the figures obtained were the same. We have more certainty as to the unit of this measurement, the Arabic mile, than in the case of the stadium, but yet not sufficient for perfect accuracy, as appears from the following definition:—According to Alfraganus the Arabic mile contained 4,000 ells of twenty-four inches, the inch being the space covered by six barleycorns laid side by side. P. Snellius compared this measure of length with one of his own units of measure, and after numerous observations found that on an average eighty-nine barley-corns are equal to a Rhenish foot. By this proportion it is found that an Arabic mile is equal to 6472 Rhenish feet. It is usual to reckon the Rhenish foot as ·16103 of a toise, and thus the mean length of the measured degree would be 58710 toises, which is too great by 1700 toises according to recent measurements. The toise is equivalent to 6·3946 feet, or 1·949040 metre.

We have mentioned already that from the decline of science we had no other than this Arabic measurement to produce, and we may further add that the most boundless ignorance, particularly with reference to natural science, reigned supreme, especially among the European nations. But it was not enough that this inaccurate determination of the size of the earth should stand as the only one for centuries; very soon it, and with it the knowledge of the spherical form of the earth was forgotten. It was not until the sixteenth century that a French physician, Fernel, again undertook the measurement of a degree. He made use for this purpose of a peculiar apparatus, which would certainly not lead us to hope for an accurate result, but, nevertheless, through fortunate circumstances, he came very near to the truth. He had a waggon constructed which, by means of a piece of mechanism, registered the number of turns made by its wheel. With this he set out from Paris in the direction of Amiens until he had gone a degree of latitude northwards, calculated from the number of turns of the wheel the linear measure, and obtained for this distance, which, according to his observation, was equal to a degree, 57070 toises. This result, as we shall see further on, agrees very closely with later observations, which is all the more wonderful from his finding the geographical latitude of Paris too little by 12′. But since this resulted from a constant error of his instrument, he must also have observed the latitude of the other end of the arc as too little by the same amount, and thus since in the calculation only the difference of the two observations is used, these errors are without any influence in the result. The other sources of error, which arose from the unevenness of the measured distance, and evidently must have given too great a result, he eliminated by subtracting a certain quantity from his calculation, and he did this so successfully that, as we have said, his result very closely agrees with modern measurements.

Another investigation at this period into the circumference of the earth, without the help of the stars, but simply by terrestrial measurements, deserves mention. Starting from a point as high as practicable (a mountain top or high tower, whose height was known), the observer went as nearly as possible in a straight line until he reached a distance at which the top of the mountain or tower disappeared in the horizon. The distance of this point from the mountain or tower was then measured, and from simple trigonometrical considerations it will be seen that the square of this distance divided by the height of the mountain or tower would be equal to the earth's diameter. But in this method the irregular action of terrestrial refraction is so disturbing, that the point at which the mountain-top would seem to vanish must be very uncertain, and the result as to the diameter of the earth consequently very erroneous.

All the methods hitherto referred to as in use in ancient times and in the middle ages, for obtaining a knowledge of the size and figure of the earth, are deficient in trustworthiness, partly from their defective theory, but still more from the impossibility of then carrying out those practical geodetic operations which are

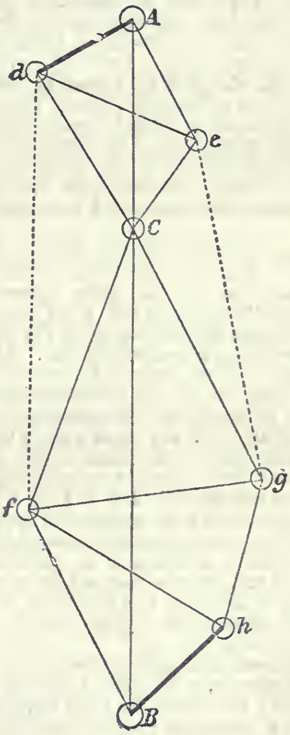


FIG. 1.

necessary for the solution of the problem with anything like accuracy. We shall see in the sequel with what wonderful accuracy it became possible to solve this important question.

The method of measuring degrees underwent, in the beginning of the seventeenth century, a fundamental reformation. Hitherto, in all such measurements, only the simplest points in the geometry of the circle had been applied, but Snellius of Leyden, making use of the properties of triangles, founded a new method for the measurement of a meridian arc, and applied it first in the year 1615—viz. the method of triangulation. His method, which has been followed ever since, possessed the invaluable practical advantage over the earlier methods, that it considerably reduced the most difficult operation in the measurement of degrees, namely, the measurement of a base line on the earth's surface. How it is possible, even in regions of very uneven surface to measure a large extent of a meridian arc with great accuracy, will be seen from the following short explanation. Suppose two places, A and B, one or more degrees of latitude distant from each other, but in the same meridian; if the unevenness of the intervening surface, from mountains and valleys, allowed of no direct measurement, one would proceed

in the following manner by the method of triangulation. First setting out from A (see Fig. 1) in whatever direction the character of the ground permits, a base-line A *d* is measured with the greatest possible accuracy. At the point A, the angle *d* A *e*, and at the point *d* the angle A *de* are observed with a circular instrument. Thus in the triangle A *de*, the adjacent side A *d* and the two other parts of the angles being known, the triangle can be computed. Place now in the straight line connecting A and B (in the same meridian) a point C, which can be seen from the points *d* and *e*; then we may, by means of the theodolite, measure at *d* and *e* the angles A *d* C and A *e* C.[1] Subtract now from these angles the previously observed angles A *de* and A *ed*, and we have now found in the second triangle, C *de*, the angles *d* and *e*. But then, also, the side *de*, as belonging to the first triangle, is known, and thus also the second triangle, and consequently its sides C *d* and C *e* are known. But if the triangles A *cd* and A *ed* are known, so are also the triangles A *d* C and A *e* C; consequently, also, the common side A C; and thus a part of the distance is measured. To obtain the length of the other part B C, a base B *h* will be measured from B, and by operations similar to the above B C will easily be found. As a test of the accuracy of the measurements, we may connect the first operation, starting from C *ed* towards *f* and *d*, and going on to B, and obtain by means of the agreement of the measured length B *h* with the calculated length of B *h* as a side of the triangle B *hf*, a proof of the accuracy of the measurements of base and angles. Should the length A B be very great and the intervening ground mountainous, a very great number of small triangles may be required: in which case, though the principle is exactly the same, yet in practice, on account of the numerous measurements necessary under such circumstances, unavoidable errors and inaccuracies will certainly accumulate.

As we have already said, Snellius, in the year 1615, was the first to measure a degree by the method of triangulation. He measured a base line on the plain between Leyden and Sonterwonde (316 Rhenish rods and 4 feet long), and by means of connected triangles obtained an arc of the meridian (between Alkmaar and Bergen-op-zoom) of 1° 11′ 30″. Although Snellius was in possession of an improved instrument (Galileo had already taught the use of the recently-discovered telescope[2] for astronomical purposes), yet his measurements were so inaccurate that he obtained far too small a result (55011 toises for a degree). He soon became convinced of the erroneous nature of his result, and seven years after repeated the operation, measuring in the neighbourhood of Leyden a base-line in the ice. Probably deterred by the multifarious and difficult numerical operations which were at that time connected with the working out of the calculation of this new measurement by means of arithmetic, he did not carry this out, but his successor, Muschenbroek, devoting himself to the execution of this work after revising the triangulation, found 57033 toises as the length of a degree in the Netherlands.

Although the method of triangulation used by Snellius was a great step in advance, yet it was a long time before it became generally adopted; for even in the years 1633 to 1635 a degree-measurement was carried out by Norwood between London and York after the old method. He used an improved instrument (a five-foot sector) and obtained as the difference in latitude of the two places 2° 28′, and the length of a degree 57424 toises. Newton, who shortly after began the elaboration of his theory of universal gravitation, did not, at all events, know this result, since he took as the basis of his researches the earlier very inaccurate results as to the dimensions of the earth, and since he found his calculations did not correspond with them he abandoned for a time his theory.

Soon after, Picard, at the instance of the Paris Academy of Sciences, undertook anew a meridian measurement, and that not only after the improved method of Snellius (since he measured all three angles of each triangle, and computed the length of the arc by pieces), but he also gave to the measuring instruments a hitherto unattained accuracy by the addition of a micrometer apparatus.[3] He measured on the meridian of Paris an arc of 1° 22′ 55″, and finding for the latitude of that place 49° 13′, with the, as we now know, wonderfully accurate result of 57060 toises for the length of a degree. When Newton, in 1682, learned the result of Picard's measurement, he resumed his calculations in gravitation, and had the satisfaction, after thoroughly revising his work, of seeing his theory of gravitation established. A few years afterwards he gave to the world his immortal work on the mechanics of the universe. For a short time Picard's dimensions of the earth were accepted as correct and were universally made use of. But while hitherto the measurements had reference alone to the discovery of the size of the earth —for its spherical form was taken as proved—there now began a new epoch in the solution of the second part of the problem—the true figure of the earth. Influenced by the fact that the length of a degree measured at different places on the earth always gave a different result—which could not in all cases be ascribed to inaccurate measurement—Picard had already broached the idea that the earth could not be a true sphere. Soon after, Newton, in his great work, showed, on the supposition that the earth existed originally in a fluid state, that on account of the rotation round the polar axis, the supposed spherical form must be more truly that of an elliptical spheroid, the polar diameter being diminished and the equatorial diameter increased. Shortly after Huyghens was led to the same result; and while Newton by his calculations found the polar diameter to be to the equatorial as 229 to 230, Huyghens, on the basis of less general theories, found the proportion to be 577 to 578. Indeed, although differing somewhat in magnitude (Newton's proportion was then accepted as the more correct), yet, in principle, they both led to the same result, viz., that the earth is flattened at the poles, so that the length of a degree near the poles must be greater than in the neighbourhood of the equator. Moreover, Newton had shown experimentally the flattening at the pole, by rotating a soft clay sphere quickly round its axis, by which it became flattened at its poles.

To this was now added another valuable proof. The French astronomer Richer, in the prosecution of his observations at Cayenne, found to his astonishment that his pendulum, which beat seconds in Paris, vibrated too slowly in Cayenne; he had to shorten it by a line in order to make it again beat seconds accurately. On his return to Paris he had to lengthen the pendulum again by the same amount, since it now went too fast. Newton perceived that this apparently insignificant fact was really of the highest importance, for he recognised that these different rates of oscillation were due in Paris to the less, and in Cayenne to the greater, distance from the centre of the earth. Cassini's discovery of the notable flattening of the planet Jupiter was an additional proof of the truth of Newton's theory. Yet it was not until the middle of last century that Newton's theory was generally accepted as an irrefragable truth.

(*To be continued.*)

[1] There is no necessity for the point C being taken in a line between A and B, nor any advantage even if it could be done. The angles need not be measured in the way here laid down.

[2] This remark seems to imply that Snellius used a telescope in measuring angles. The application of the telescope to circular instruments was a step taken by Picard.

[3] Picard adapted to his measuring instrument a telescope with cross-wires in its focus; this appears to be the only "micrometer apparatus."

THE VARIOUS METHODS OF DETERMINING THE VELOCITY OF SOUND

THE propagation of sound is a question with many bearings in the province of physics, and the researches of physicists in relation to it, though numerous, have left some points still under discussion. It is useful in the view of further inquiry to be furnished with a historical survey of what has been already done, and this is the object of a recent memoir by Dr. H. Benno-Mecklenburg, published in Berlin (a *résumé* of which to the following effect appears in the May number of the *Journal de Physique*).

The author has adopted the following classification of the methods that have been employed for measuring the velocity of sound:—

I. Methods requiring the measurement of a time and a course traversed.

1. Direct measurement of the velocity; the most ancient measurements of this kind were executed by P. Mersenne in 1657, by the Academicians of Florence in 1660,[1] by Walker[2] (in England), in 1698; by Cassini and Huyghens (in France), &c.

2. Method of coincidences, indicated by Bosscha,[3] and employed by Koenig.[4]

[1] Newton, "Philosophia Naturalis Principia Mathematicæ," II., Prop. XLVIII.-L.

[2] Laplace, "Mécanique Céleste," t. v. livre xii. p. 115.

[3] Tentamina, "Exper. Academ. del Cimento," 1738, xi. p. 116.

[4] *Philosophical Transactions*, 1698.

3. Apparatus of Neumann[1] and Le Roux.[2]

II. Estimation of the velocity of sound by the number of vibrations and the wave-length of musical sounds.

A. Direct methods :—

1. Method of Bernouilli, with sonorous tubes.
2. Method of Chladni,[3] with rods.
3. Method of Kundt.
4. Methods of Stefan[4] and Warburg.[5]

B. Methods based on the interference of sonorous waves :—

1. Method of Savart.[6]
2. Method of measurement of the wave-length with Quincke's interference tubes.[7]
3. Method of Zach.[8]
4. Method of beats.

The way in which the velocity of sound is affected by certain circumstances, especially intensity and pitch, requires further elucidation. Up till recent times it was believed, in accordance with the earlier observations and the theoretical formulæ of Newton and Laplace, that sound is propagated with a uniform velocity in the same medium, the temperature remaining constant; that the velocity of sound in air at zero, *e.g.*, is an invariable quantity. After an observation by Parry related by Sir James Ross, that the sound of a cannon was always heard sooner than the word of command to fire, Schröder van der Kolck was led by theory to a formula giving the velocity of sound in a gas as a function of the relation of the two specific heats and the degree of compression of the medium. This velocity would be greater the more intense and grave the sound, and would diminish with the distance traversed.

Regnault set himself to determine rigorously the ratio of the two specific heats of gases, with a view to deducing the mechanical equivalent of heat. He remarked that Newton and Laplace had assumed, in their formulæ, that the gases were perfect, *i.e.* (1), that they followed Mariotte's law exactly; (2) that their elasticity was not altered by surrounding bodies; and (3) that gas opposes no inertia to the transmission of sound-waves. Accordingly the propagation of sound was supposed the same whatever the intensity. Regnault's more complete formula indicated that the velocity is greater the greater the intensity of the wave.

Experiment proved that the intensity of the wave diminishes in a tube more rapidly the smaller the section. The wave is weakened by the reaction of the elastic walls of the tube, causing a considerable loss of *vis viva;* and the diminution of intensity, according to Regnault's formula, should result in diminution of velocity, which diminution must be more rapid the narrower the tube. This was confirmed by experiment.

As regards experiments with the human voice and wind-instruments, the following are the principal observations of Regnault; acute sounds are propagated with much less facility than grave sounds; in very wide pipes, it is necessary to sing with a baritone voice in order to be well heard; the fundamental sound is heard before its harmonics, which succeed in order of pitch, and the timbre is thus altered. The velocity was found independent of pressure, as indicated by the formulæ. Lastly, with different gases, the velocities are inversely proportional to the square roots of the densities.

In connection with the foregoing, it is interesting to compare the results that have been obtained by Kundt.[9] The idea of his method was suggested by Chladni's figures. A tube of glass is used about 2 m. long, containing a certain quantity of lycopodium powder (distributed as regularly as possible), and closed at the two ends. You rub the tube longitudinally, so as to produce a sound. The powder is then seen to accumulate at the nodes of vibration, so that the sonorous waves of the gas are, in a way, rendered visible. The distance from one node to the next being half a wave length, suppose that we have twelve in the tube; the length of the tube vibrating transversely, will be the half of a wave-length in the *glass.* Under such conditions, then, the length of half a wave in the glass is sixteen times the length of half a wave in the air. It will follow that the velocity of sound in the glass is sixteen times that in air. Other gases may be used in the tube, and the velocity of sound similarly found in them.

By a simple modification of the apparatus, this method gives the velocity of sound in a large number of solid bodies, and the results agree pretty closely with those found by different methods.

But Kundt's method does not give sufficient precision in respect to the delicate questions investigated by Regnault. The wave-lengths measured never go beyond about 45 mm., making the 0·0001386 part of the course traversed by sound in a second; hence an error of 0·1 mm. made in the measurement of a wave-length would lead to an error of $\frac{11}{16}$ m. in the result sought. With this reserve, Kundt's results may be here noted.

1. The length of sonorous waves, and consequently the velocity of sound, diminishes proportionally to the diameter of the tube, when this is less than a quarter of the length of undulation.
2. In narrow tubes a high sound is transmitted more rapidly than a grave one, and the diminution of the velocity of sound is in inverse ratio to the wave-length.
3. The velocity of sound is independent of the pressure in a wide tube, but increases with it in a narrow one.

It will be seen that these latter results are in contradiction with those found by Regnault.

It may be generally affirmed that every influence which tends to increase the *vis viva* of the molecules of the sonorous medium has an accelerating action on the velocity of sound, and every influence tending to diminish the *vis viva* diminishes also the velocity.

The causes affecting the velocity of sound are (it is shown) various. *In an indefinite medium* they are :—1. The temperature of the medium; 2. The quantity of foreign substances found in it, *e.g.*, water-vapour; 3. The pitch of the sound; 4. The direction and force of the wind; 5. In solid bodies, the direction of the sound in relation to the molecular structure.

In sonorous tubes :—

6. The diameter; 7. The curvature; 8. The rugosity of the interior surface; 9. The thickness of the walls.

The action of the following additional causes is still disputed :—

1. The intensity of the sound; 2. The length of course traversed; 3. The substance forming the tubes.

There is complete disagreement between Regnault, Schröder, Kundt, and Seebeck, as regards the influence of the pitch of the sound. Regnault affirmed merely that an acute sound is transmitted more easily, but not more rapidly, than a grave sound; Schröder finds that the velocity diminishes as the acuteness increases; Kundt and Seebeck reach the contrary result. Fresh experiments are required to settle this important question.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE

A NEW supplemental charter having been granted to the University of London a few months since, on the joint application of the Senate and of Convocation, empowering the Senate to admit women to graduate in its several faculties (Arts, Science, Law, Medicine, and Music), on such conditions as the Senate, with the concurrence of the Home Secretary, should deem expedient, the Senate lost no time in passing a resolution which made all the existing regulations, relating not only to graduation, but also to the various honours and rewards granted at the several examinations open to female as well as to male candidates. This resolution having been now approved by the Home Secretary, female candidates will be admitted forthwith to the matriculation examination; and all such as have already passed the general examination for women will be considered as having matriculated, and will be admissible (after the required interval) to the first degree examination in either of the faculties. Further, with a view to the special encouragement of female candidates desiring to go through a regular academical course, the trustees of the Gilchrist Educational Trust have instituted two exhibitions, one of 30*l.*, the other of 20*l.*, per annum, tenable for two years, to the female candidates who pass highest in the honours division at the matriculation examination; and two exhibitions, one of 40*l.*, the other of 30*l.*, per annum, tenable for two years, to the female candidates who pass highest at the first B.A. examination (provided that they obtain in the first case two-thirds, and in the second three-fifths, of the total number of marks), to assist them in pursuing their studies at some collegiate institution approved by the trustees; with the further reward of a gold medal of the value of 20*l.* (or of a book-prize of the same value) to the female candidate who passes highest at the second B.A. examination, if she obtains not less than two-thirds of the total number of marks. These rewards are quite independent of those granted

by the University, and may be held in conjunction with them. Further particulars may be obtained by application to the Registrar of the University, London, W.

SCIENTIFIC SERIALS

Annalen der Physik und Chemie, No. 7, 1878.—Theory and experiment having given different results for the heat-conduction of certain (polyatomic) gases, Prof. Wüllner supposed the reason to be that the values were not comparable, because they related to different temperatures. He shows from experiment that the ratio of the two specific heats varies with the temperature. For those gases whose specific heat at constant pressure does not vary with the temperature, the variation is of about the same order as the divergence of gases from Mariotte's law. For gases, whose specific heat varies with the temperature, the ratio of the specific heats varies in a greater degree, and approximately so that the difference of the specific heats at 0° and 100° is constant. Herr Wüllner finds here an explanation of the discrepancy.—In a lengthy paper Herr Hittorf vindicates the affirmation that "electrolytes are salts," in reply to Dr. Bleekrode's criticism. We note, also, papers on the energy of reciprocal action, by Herr W. Weber, and on the law of storms, by Herr Schröder.

No. 8.—This number opens with a paper by Herr Herwig, on the amount of electricity required for full charge of a condenser platina water-cell, and on the distance of the molecules in liquid water. The upper limit he deduces for the latter is 0·186 millionth mm.; which agrees well with other determinations, Lorenz 0·1 millionth mm., Thomson (for lower limit) 0·05. He finds in the result a confirmation of the hypothesis of rotatable electrolytic molecules.—In a paper on the wandering of ions, M. Kirmis shows that the amount of transference of copper from the solution of its sulphate salt increases with decreasing concentration.—Investigating the history of the invention of the pendulum clock Herr Gerland considers that Bürgi and Treffler have not the least claim to this merit. It belongs to Galileo and Huyghens, who made the discovery independently. As the former, however, came on it fifteen years earlier, the pendulum clock is properly his work.—Herr Auerbach endeavours to show that Grossmann's vowel theory applies not to actual vowels, but to typical ideal clangs, and when the changes thus rendered necessary are introduced into it, it affords, if not incorrect results, nothing new as against Helmholtz's theory.—Herr Bauer has a paper on summation tones as difference and beat-tones from the over-tones of the primary tones; and Herren Nilson and Pettersson write on the production and valence of beryllium.

Journal de Physique, August, 1878.—In this number M. Bouty explains the construction and use of electric diagrams, for representing as completely as possible all the peculiarities of an electric field.—Some curious experiments with the electric tourniquet are described by M. Bichat.

SOCIETIES AND ACADEMIES

Paris

Academy of Sciences, September 9.—M. Fizeau, president, in the chair.—The following papers were read:—On some phenomena of a vaso-motor action observed in the course of researches on the physiology of the excito-secretive nerves, by M. A. Vulpian.—On some new effects produced by the telephone, by M. du Moncel.—On the new palæozoic group of Dolerophylleæ, by M. G. de Saporta.—On a new gyroscopic apparatus, by M. Gruey.—On the accumulation of magnetism on the summit of hemispheric poles, by M. L. Romain.—On the waves of the high sea, by M. Ch. Antoine.—Some notes, by MM. Vasseur, Lassalle, and Cameron, regarding aerial navigation.—An additional paper by M. Giraud respecting the treatment of cholera.—A note by M. F. Bettelhauser respecting the various means employed for the destruction of phylloxera.—Prof. Asa Gray, who has been nominated a correspondent of the Botanical Section, presented the first part of his "Synoptic Flora of North America."—Rectification of the position previously assigned to the new planet discovered during the eclipse of the sun on July 29, by Prof. J. Watson, and note on the observation of a second star seen under the same circumstances.—On a new method to decompose numbers into square binary sums and its application to indetermined analysis, by M. E. de Jonquières.—On the depression which, at the surface of a horizontal elastic and isotropous ground, is produced by a weight deposited thereon, and on the distribution of this weight between its various points of support, by M. J. Boussinesq.—On the variations of intensity which take place in a current if the pressure between the two contacts, which complete the circuit is modified, by M. THE SUPERFICIAL GEOLOGY OF SOUTH-WEST LANCASHIRE

The Superficial Geology of the Country adjoining the Coasts of South-West Lancashire. By C. E. De Rance, F.G.S. 1877.

THE memoir of the Geological Survey by Mr. De Rance recently published is an interesting contribution to our knowledge of the superficial deposits of the area between the Mersey and the Ribble, which carries the classification of the Cheshire Plain as far to the north as Morecambe Bay. The whole of this district is covered with glacial drift and recent sands, gravels, and peat-bogs, except here and there where the solid rocks come to the surface in the hills. The drift forms an inclined plane dipping from the hills towards the sea, and probably deposited during subsidence upon an old rocky plain of marine denudation, bounded to the east by a line passing from Eccleston to Euxton and Ribchester, and thence through Broughton, Garstang, and Cockerham to the present sea-margin. Were the superficial deposits stripped off this area, the rock-surface would be seen to be not very far from the present sea-level, although the surface of the ground is often 170 feet above it. This plain also dips gently seaward, and has been worn into hollows by the denuding forces before the glacial period. Very generally it has been cut up into hills and valleys by pre-glacial streams, as, for example, the buried valley of the Mersey described by Mr. Mellard Reade, now filled with 200 feet of sands, gravels, and clays. These buried valleys may be traced inland, rising nearer to the present surface of the ground as we approach the high ground, until at last their tributaries come to the active surface in the higher hills, and are traversed by the same streams as those now finding their way to the surface, and through the accumulation of drift filling their ancient lower courses. It seems tolerably certain that the hill and valley system of Lancashire and Cheshire was produced by sub-aërial agents before the glacial period, and that the ice merely acted on the solid rock by rounding off and smoothing the raw edges left by the streams and rivers. Indeed, as a rule, it may be said that the relative importance of the agency of rain and rivers, and of ice in scenery making is precisely that of chisel and sand paper, the one carves, while the other rounds off, smooths, and polishes. But whatever view may be held of the cause of this uneven surface below the mantle of the drift, it is a most important fact to be noted, that the surface configuration bears little or no relation to the rock-surface below, as engineers have frequently found out by experience in making reservoirs. In one case, for example, the "puddle trench" had to be carried down 160 feet, so as to render a ravine filled with drift water-tight, and this ravine, with the big boulders at the bottom left in the bed of the stream, by which it was hollowed, was intercepted twice in the course of the works.

The drift of the district under consideration is treated by Mr. De Rance in three divisions, the lower and upper boulder clays, separated from each other by the middle glacial marine sands and gravels. There appears to be no important physical difference between these clays, and their relative age can only be ascertained by their relation to the sands above mentioned. This, however, is not an infallible guide, because there are lenticular strata of sand and gravel intercalated here and there in the boulder clays. According to Mr. De Rance they are absent from the base of the lower boulder clay, a position which Mr. Binney has shown them to occupy in other districts in Lancashire and Cheshire. Our author notices also the glacial striæ, *roches moutonnées*, and the moraines on the higher grounds overlooking his area, and points out very justly (p. 46) that "the till" and "lower moraine drift" of other districts may have been formed at the same time that the lower boulder clay was being accumulated. It may also be pointed out that the local glaciation of North Wales and of the Pennine chain, and of the hills of Cumberland may have been produced while the upper boulder clay was being formed. Nevertheless, we cannot obtain an accurate idea of the relation of the various glacial phenomena to one another in point of time in different parts of Britain, until we can ascertain the sequence and extent of the changes of level, which has not as yet been made out. To my mind three great changes only have been proved to have taken place over a wide area: two periods when Britain stood at a higher level than it does now, with an intervening period, during which the region north of the lower Thames and Severn was submerged to a depth of 1,200 to 1,500 feet on the flanks of Snowdon. There were three corresponding climatal changes, the first period of elevation being marked by a very low temperature; the second, or that of depression, by temperate conditions; and the third or last period of elevation being also marked by severe climatal conditions. It is obvious that, during changes such as these, the sands, gravels, and clays, termed "glacial drift," would be so extremely complicated and so various in different places, that it is difficult, if not impossible, to ascertain the contemporaneity of the more minute sub-divisions of the glacial strata. While sands and shingle were being accumulated along the coast-line, melting icebergs were dropping their burdens to form boulder-clays in the adjacent sea, and on the land the moraines of the retreating glacier were being heaped together, or the advancing glacier was ploughing its way downwards. All these operations were going on simultaneously in different parts of the glacial area of Great Britain, and their results are rendered infinitely more complex by the oscillations of the level of the land, which may have been local, and by changes of climate as yet imperfectly understood. From these considerations it is evident that the clays and shingles and sands cannot be severally classified together, excepting in the strict *homotaxial* sense, and apart from all ideas of contemporaneity, and that the sequence of the minute divisions of the glacial period in Scotland, published by Dr. James Geikie in his able work, and based upon the relation of clays to sands and gravels, cannot in the nature of things apply to Lancashire, or any other areas beyond Scotland. Mr. De Rance has acted prudently in confining his attention to the drifts of the area treated in the memoir without dealing with the general question, which, to my mind, is

not yet sufficiently known to be dealt with in any other fashion than that of the threefold classification of Ramsay, Jamieson, and Lyell. The refinements on this classification attempted by several authors are based upon phenomena which have not yet been proved to be other than local.

One of the more interesting sections of this memoir relates to the growth and accumulation of peat; the author's conclusion that the rate at which peat grows is very uncertain and dependant on local conditions, is confirmed by the recent researches of Dr. Angus Smith, and his observations regarding the manner in which forests have been destroyed by its growth are probably true. The presence, however, of large oaks at great elevations in Britain need not necessarily "point to warmer summers than at present," but may be accounted for by the fact of their having grown in a primeval forest, one under the shelter of another, thus attaining a height and reaching a size which they could not do on our bare hills exposed to the high winds. An example of this may be seen in the fine tall trees growing in the sheltered valley in which Furness Abbey stands, as compared with the stunted growth on the exposed hill-sides around. Nor can the Scotch firs on the peat of the south of England be taken to prove the inclement winters of the prehistoric period, since they now flourish also in the south of England at levels but little above the sea. For the same reason also the peat bogs cannot be looked upon as proving a lower temperature then than now. In Somersetshire the turf moss extending from Glastonbury to Highbridge is growing at the rate of from 4 to 6 feet in fifteen years, so that the places where the peat is cut are filled up in that time. These, however, are unimportant points in a valuable memoir which deals with the district in a very comprehensive manner and in a small space.

It should be remarked, in conclusion, that the price of 17*s*. for a small octavo of 139 pp. in paper wrappers is without precedent and unreasonable, and that the policy of absurdly high prices for Survey Memoirs, which, as it appears from the two last publications, is being pursued by the Stationery Office, is certain to restrict the sale, and thus render them comparatively useless. They cannot be expected to pay their cost any more than the Reports of Parliamentary Commissions; they ought to be issued at a mere nominal sum, and distributed with a liberality like that shown in similar cases by the American Government.

W. BOYD DAWKINS

SCIENTIFIC HORTICULTURE

The Parks and Gardens of Paris. By W. Robinson, F.L.S. Second Edition, Revised. (London: Macmillan and Co., 1878.)

THE Science of Horticulture are words often used and too often misused. That there is science in horticulture, or that it is capable of being based on scientific principles, cannot be denied. There is sufficient in the cultivation of plants and flowers, and in their proper disposition in the garden, to occupy a highly refined and cultivated intellect. A garden, according to its dimensions and capabilities, has always been, and is still, more or less a delight to its owners. Like everything else, the taste exercised in the science of gardening has in different ages shown itself in various ways. The hideous clipping of hedges and shrubs into the forms of animals, birds, &c., still occasionally to be seen in some old English gardens, are records of one of the worst periods of gardening in this country, and the modern system of carpet or ribbon bedding, aptly termed by Mr. Robinson the "coloured cotton handkerchief" style, is not one whit more defensible, but rather, we should say, even more reprehensible, considering what has been done and written of late with the view of elevating public taste in matters of science and art generally.

To no book can we point with so much satisfaction on the subject of laying out or grouping plants or trees in parks or gardens as to that which now lies before us. No writer on this, or on kindred subjects, has discoursed more pleasantly than has Mr. Robinson. That his theme has inspired his pen as that of a ready writer is self-evident; and that he is a true lover of plants for their own sake is also apparent from his frequent references to individual species. But he is something more than this, for it will be found from a perusal of his book that he possesses a thorough knowledge of his subject.

It must not be imagined from the title of the book that the parks and gardens of Paris are, in their entirety, held up for our admiration and imitation. On the contrary the author distinctly points out, and separates the good from the bad, the true from the false, retaining, so to speak, the wheat and consuming the chaff with the fire of a powerful criticism. Notwithstanding this, there can be no two opinions as to the general superiority of the French capital over that of our own in point of picturesque beauty. No visitor to Paris—and no one probably has ever visited that city without visiting also the Bois de Boulogne—can have failed to compare in his own mind the sylvan beauty of the Bois, and the ragged uncared-for appearance of our own London parks; and the contrast is even greater in the squares and gardens of the two capitals, and yet as Mr. Robinson points out, there are excellent sites and splendid opportunities in London to make it a city suitable for other purposes besides those of business and toil. To properly effect this of course architecture and horticulture must join hands. Nevertheless much depends upon a proper provision by the architect for the horticulturist and landscape gardener to exercise their skill. As an illustration of how this may be done, Mr. Robinson draws attention to the new avenue between the new Opera House and the Rue de Rivoli in Paris, and points out that they "have not only been made without cost to the town, but even with a balance on the right side, the vastly increased value of sites for business premises in these new and noble streets having more than repaid the cost of their formation and the removal of the old houses through which they were driven. Abroad, every little capital possessing enough interest to occupy one for two hours, is furbishing up its attractions, while we in London are neglecting advantages the like of which are not possessed by any other city in Europe. The river, the bridges, the suburbs, the surroundings are infinitely superior to Paris, but owing to stupid absence of plan many of the good points are lost, many of the best suburbs being unknown ground even

to thousands of Londoners owing to the impossibility of reaching them without struggling through narrow and mean streets and roads."

The first chapter of Mr. Robinson's book opens with a consideration of the Bois de Boulogne, and from it we may learn much that is good both in the way of artistic grouping, planning, and in the selection of individual plants. Unlike what we too often see in public parks and gardens, the vegetation along the banks of the lakes in the Bois is properly diversified, "so that at one place we meet with conifers, at another rock shrubs, at another magnolias, and so on, without the eternal repetition of common things which one too often sees." The author next proceeds to point out the great advantage of permanent planting over that of plants which show only a fleeting annual display. In spring the early bloom and budding leaves are in themselves things of beauty, and are even more so when seen collectively or in company with each other. In summer they furnish an infinite variety of form and consequent depth of tone, while in autumn "the number and richness of the tints of the foliage afford a varied picture from week to week, and in winter the many graceful forms of the deciduous trees among the evergreen shrubs and pines offer as much to interest an observant eye as at any other season."

On the subject of sub-tropical gardening, which is well exemplified in the Park Monceau, the author writes in his pleasantest manner, as the following extract will show:—"We may be pleased by the wide spread of purple on a heath or mountain, but when we go near and examine it in detail we find that its most exquisite aspect is seen in places where the long moss cushions itself beside the Ling, and the fronds of the Polypody peer forth around little masses of heather. Everywhere we see nature judicious in the arrangement of her highest effects, setting them in clouds of verdant leafage, so that monotony is rarely produced—a state of things which it is highly desirable to attain, as far as possible, in the garden. We cannot attempt to reproduce this literally, nor would it be wise or convenient to do so; but assuredly herein will be found the chief source of true beauty and interest in our gardens; and the more we keep this fact before our eyes the nearer will be our approach to truth and success.

"We should compose from nature, as landscape artists do. We may have in our gardens—and without making wildernesses of them—all the shade, the relief, the grace, the beauty, and nearly all the irregularity of nature. This bold growth of 'fine-foliaged plants' has shown us that one of the greatest mistakes ever made in the garden was the adoption of a few varieties of plants for culture on a vast scale, to the exclusion of interest and variety, and too often of beauty or taste. We have seen how well the pointed, tapering leaves of the cannas carry the eye upwards; how refreshing it is to cool the eyes in the deep green of those thoroughly tropical castor-oil plants, with their gigantic leaves, how noble the Wigandia, with its fine texture and massive outline looks, after we have surveyed brilliant lines and richly painted leaves; how, too, the bold tropical palm leaves beautify the garden. In a word, the system has shown us the difference between the gardening that interests and delights all beholders, and not the horticulturist only, and that which is too often offensive to the eye of taste and pernicious to every true interest of what has been called 'the purest of human pleasures.'"

Notwithstanding the general interest kept up throughout Mr. Robinson's book, no part is of greater interest than the chapter on the cultivation of mushrooms in the caves under Paris, where, at a depth of from sixty to eighty feet below the surface of the ground, in old stone quarries, this edible fungus is grown systematically on a very large scale. These caves furnish not only the daily supply of the Paris markets, but to a large extent those of England and other countries also, preserved mushrooms to the extent of 14,000 boxes annually being exported to this country by one house alone. It is estimated that in and around Paris the daily production of mushrooms amounts to about twenty-five tons, of the value of about 1,000*l.*, or close upon 400,000*l.* per annum. One large grower near St. Denis is described as employing nineteen horses and fifty men. Mushrooms are very extensively used in France, not only in their fresh state, but preserved in various ways, either by tinning, bottling, preserving in butter or oil, or reducing to powder.

The book is exceedingly well printed and carefully got up.

OUR BOOK SHELF

Elements of Physiography. By Prof. D. T. Ansted, M.A., F.R.S. (Allen and Co.)

We are glad to see a book on physiography from the pen of Prof. Ansted, whose name has so long been associated with the literature of physical geography. If the new subject, however, is to be treated as it is in the present work, we fail to see the advantage of any change. The distinctive parts of physiography are all got through in an introduction of some eighteen pages, which we fear are too much written up to the *ipsissima verba* of the syllabus issued by the Science and Art Department to be of much educational value.

And, in fact, it is on this point that we find most fault with the book. Take these two paragraphs concerning aqueous vapour, pp. 101, 102, and note the absence of the why in every case.

"Aqueous vapour is frequently rendered visible as mist, fog, or cloud. These are varieties of the same condition. Mist is formed when currents of air of different temperature, both containing invisible vapour, meet near the earth. In valleys such mixtures are very frequent, and in mountainous countries very striking. Fogs are formed in the same way in temperate climates at various seasons, and hang over shores and the mouths of certain streams.

"Clouds are produced when mixtures of currents take place at some distance above the ground, and the visible vapour is entirely detached from the earth. There are several varieties of clouds, some floating at a height of many miles, some hovering in large masses in mid-air, some drooping downwards and almost touching the earth. They are rarely alike long together. They assume, as we know, the most fantastic shapes, and are occasionally decorated with brilliant tints of colour! It is only the clouds that form in large masses and approach the earth that dissolve into heavy and long-continued rain, but all clouds are capable of yielding rain, and drops sometimes, though rarely, fall through air perfectly clear and cloudless."

A student had better not be taught at all than be taught in this manner, and, in fact, a student of average intelligence, after reading such a string of assertions without the least

attempt at explanation—while everyone of them might have been made part of his nature for ever afterwards, by giving the simple reason in each case—if he does not doubt the competence of his teacher, will have no more to do with him.

La Spectroscopie. By A. Cazin. (Paris: Gauthièr-Villars.)

THE talented author of this work has passed away since the MS. was completed. This is by no means a systematic treatise, but it contains a large amount of information—some of it out-of-the-way information—and it will repay perusal. As much of M. Cazin's information on the celestial applications has been gathered from Secchi's works its complete accuracy is not to be relied on, but the explanation given of the different methods employed is very clear.

The part of the book which perhaps will be read with the greatest interest is that dealing with radiation and absorption spectra. In this part the author includes a notice of much of his own work, which is of great interest and importance. The *historique* of the question as to the existence of double or multiple spectra is interesting, and the author's leaning is against the view held by Ångström and Thalèn. He gives special observations of his own concerning nitrogen, and indeed was engaged on an extension of them at the time of his lamented death.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to ensure the appearance even of communications containing interesting and novel facts.*]

Sun-spots and Rainfall

IF the sun-spot cycles were all of the same length the simplest way of comparing the yearly sun-spot areas with the yearly amounts of rainfall in order to see whether the two phenomena were more or less numerically related, would be to find the annual means of the greatest possible number of cycles, care being taken to place the years of maximum and minimum in the same two groups respectively, and the intervening years in due succession. But as the sun-spot cycles are not of the same length, we must in employing the method of arithmetical means, make some modifications calculated to suit the circumstances of the case.

1. We may, for example, take any cycle whatever may be its duration, and commencing with its first and ending with its last year, compare with the sun-spots the rainfall at any station, or the means of the rainfall at a number of stations for the same years.

2. If some of the cycles be of the same length, we may take these alone and compare them with the rainfall, still taking care that the years of maximum and minimum sun-spots shall be respectively in the same groups.

3. The average length of the sun-spot cycle being, as far as is yet known, about eleven years, we may take any number of cycles of different lengths and make two separate comparisons, in one of which the maximum years are to be placed in the same group, and in the other the minimum years in the same group, the number of the other groups preceding and following the epochal groups being determined by the fact that the mean interval from minimum to maximum is about 3·7 years, and from maximum to minimum about 7·4 means.

I have tried these and several other methods, with, I think, considerable success. The method just mentioned (3), which is the old one of arithmetical means somewhat modified to meet the conditions of the case, possesses several advantages, one of the most important of which is that it enables us to compare directly the rainfall with the sun-spots in the epochal years, and in at least two years before and two years after them, thus affording a fair comparison for nearly the whole cycle of eleven years—a most essential point, which, it would appear, has been overlooked by some writers on the subject.

Having in my last communication (NATURE, vol. xvii. p. 448) given an example of the first half of the above method, together with the results obtained by it for several localities, I intended on this occasion to submit only one or two examples of the second half. But finding that the method has been criticised by Mr. Buchan, and having now Prof. Wolf's latest edition of his relative sun-spot numbers, as well as the rainfall of Madras for 1877, it may be proper to give instances of the application of the whole process.

Let us begin with Wolf's relative numbers, which are so arranged in the following table that those for the years of maximum sun-spot, from 1811 to 1877, are all in the sixth line. This table has already been given by Mr. Buchan (NATURE, vol. xvii. p. 506), but as references will be made to it now, and also in future discussions of the rainfalls of various parts of the globe, it is desirable to reproduce it here.

TABLE I.—*Wolf's Sun-spot Numbers (Maximum Years in Sixth Line).*

Year.	1811–1823.	1824–1836.	1832–1844.	1843–1855.	1855–1867.	1865–1877.	Means.	Mean Cycle.	Variation.	Year of Cycle.
1	1·6	8·1	26·3	13·1	7·7	31·4	14·7	—	—	—
2	4·9	16·2	9·4	19·3	5·1	14·7	11·6	14·9	−33·9	1
3	12·6	35·0	13·3	38·3	22·9	8·8	21·8	25·4	−23·4	2
4	16·2	51·2	59·0	59·6	56·2	36·8	46·5	48·8	0·0	3
5	35·2	62·1	119·3	97·4	90·3	78·6	80·5	77·0	+28·2	4
6	**46·9**	**67·2**	**136·9**	**124·9**	**94·8**	**131·8**	**100·4**	**91·9**	**+43·1**	**5**
7	39·9	67·0	104·1	95·4	77·7	113·8	83·0	83·0	+34·2	6
8	29·7	59·4	83·4	69·8	61·0	99·7	65·7	65·6	+16·8	7
9	23·5	26·3	61·8	63·2	45·4	67·7	48·0	49·0	+ 0·2	8
10	16·2	9·4	38·5	52·7	45·2	43·1	34·2	34·6	−14·2	9
11	6·1	13·3	23·0	38·5	31·4	18·9	21·9	24·6	−24·2	10
12	3·9	59·0	13·1	21·0	14·7	11·3	20·5	22·5	−26·3	11
13	2·6	119·3	19·3	7·7	8·8	7·0	27·5	—	—	—

It will be seen that each of six of the columns in the above table gives the sun-spot numbers for thirteen years, and that the first term of what is called the "mean cycle" is obtained from the expression, $\frac{a + 2b + c}{4}$, where a, b, c, are the means of the sun-spots for the first, second, and third years of the thirteen years, the remaining terms being obtained in a similar manner. The "variation" is simply the deviations from the mean value of the sun-spots for the "mean cycle."

The next table gives the sun-spot numbers, from 1816 to 1872, arranged so that the minimum years are in the eighth line:—

TABLE II.—*Wolf's Sun-spot Numbers (Minimum Years in Eighth Line).*

Year.	1816–1828.	1826–1838.	1836–1848.	1849–1861.	1860–1872.	Means	Mean Cycle.	Variation.	Year of Cycle.
1	46·9	35·0	119·3	95·4	94·8	78·3	—	—	—
2	39·9	51·2	136·9	69·8	77·7	75·1	73·1	+ 23·3	1
3	29·7	62·1	104·1	63·2	61·0	64·0	64·3	+ 14·5	2
4	23·5	67·2	83·4	52·7	45·4	54·4	54·6	+ 4·8	3
5	16·2	67·0	61·8	38·5	45·2	45·7	44·2	− 5·6	4
6	6·1	59·4	38·5	21·0	31·4	31·3	30·8	− 19·0	5
7	3·9	26·3	23·0	7·7	14·7	15·1	17·3	− 32·5	6
8	**2·6**	**9·4**	**13·1**	**5·1**	**8·8**	**7·8**	**12·7**	**− 37·1**	**7**
9	8·1	13·3	19·3	22·9	36·8	20·1	24·4	− 25·4	8
10	16·2	59·0	38·3	56·2	78·6	49·7	51·6	+ 1·8	9
11	35·0	119·3	59·6	90·3	131·8	87·2	80·7	+ 30·9	10
12	51·2	136·9	97·4	94·8	113·8	98·8	94·6	+ 44·8	11
13	62·1	104·1	124·9	77·7	99·7	93·7	—	—	—

We can now compare the rainfall of Madras with the values of the sun-spots in Tables I. and II., except for the years 1811 and 1812, for which there are no observations:—

TABLE III.—*Rainfall of Madras* (*Maximum Years in Sixth Line*).

Year.	1811–1823.	1824–1836.	1832–1844.	1843–1855.	1855–1867.	1865–1877.	Means.	Mean Cycle.	Variation.	Year of Cycle.

8	76.2	44.3	53.1	36.9	38.2	73.7	53.7	50.4	+ 1.9	7
9	36.3	18.4	58.6	64.3	54.6	51.8	47.3	51.5	+ 3.0	8
10	70.0	*37.1	58.3	72.7	47.2	62.9	58.0	50.7	+ 2.2	9
11	47.1	39.0	36.5	35.8	41.6	37.1	39.5	45.4	− 3.1	10
12	59.6	41.5	*50.3	43.2	51.4	21.5	44.6	42.1	− 6.4	11
13	*26.6	44.8	65.4	32.3	*24.4	45.0	39.7	—	—	—

The "mean cycle" in the above table has been formed (in the way already mentioned) with the view of reducing the effects of what are called "accidental" irregularities in the rainfall, and its mean value is 48.5 inches, while the mean of the thirteen "means" is 47.3 inches. Now it will be observed that, as was the case when only the years 1813 to 1867 were taken (NATURE, vol. xvii. p. 449), there is apparently a double oscillation of the Madras rainfall during the sun-spot cycle. It will be seen also—and it is important to bear this point in mind—that the mean rainfall of the seven maximum years not only does *not* exceed, but barely reaches, the mean for the whole cycle. There are apparently two maxima and two minima, and one of the minima seems to occur very soon after the sun-spot maximum. In fact, there was a great deficiency of rainfall at Madras in the maximum year 1860, and in the years 1830, 1861, and 1869, immediately following or preceding a maximum year, but whether there were famines in one or more of these years, I do not know. (The years of minimum sun-spots are marked with an asterisk.)

Coming now to the second half of the method, so far as Madras is concerned, we get the following results :—

TABLE IV.—*Rainfall of Madras* (*Minimum Years in Eighth Line*).

Year.	1816–1828.	1826–1838.	1836–1848.	1849–1861.	1860–1872.	Means	Mean Cycle.	Variation.	Year of Cycle.

11	60.7	44.8	79.8	55.1	*74.1	62.9	57.4	+ 8.4	10
12	88.4	*49.3	81.0	*27.6	56.3	60.5	58.8	+ 9.8	11
13	37.9	52.3	*54.8	37.2	73.7	51.2	—	—	—

The above table shows that the minimum rainfall, both for the "means" and the "mean cycle," coincides with the minimum of sun-spots (see Table II.), and that, upon the whole, the spots and the rain decrease and increase together. But as the maximum years (with an asterisk) are not all in the same line, nor the minimum years in Table III., all in the same line, it is necessary to confine our attention to the results for about two years on either side of the epochal years in Tables III. and IV., and in doing so we find evidence of a double oscillation.

To ascertain whether there is some probability of such an oscillation in the rainfall of Madras, we must have recourse to the more efficient method of the harmonic analysis. I have not had leisure to do so in this particular case, but Mr. J. Allan Broun (NATURE, vol. xvi. p. 334), in a thorough examination of the rainfalls of Madras and Trevandrum for the years 1838-76, gives for the mean oscillations of the Madras rainfall during that period the following equation, where y is the mean yearly rainfall in inches :—

$$y = 5.4 \sin (\theta + 50°) + 4.6 \sin (2\theta + 252°) ;$$

and he remarks that these angles give the epochs of *minimum* rainfall both in the years of minimum and of maximum sun-spots, and that the single oscillation (of about five years) has held good in seven successive periods. Now this is nearly what we should expect from Tables III. and IV.

Leaving the Madras rainfall for the present, let us come to that of Edinburgh for the years 1824 to 1872. The following table gives a comparison of the Edinburgh rainfall with the sun-spots from 1824 to 1867 :—

TABLE V.—*Rainfall of Edinburgh* (*Maximum Years in Sixth Line*).

Year.	1824–1836.	1832–1844.	1843–1855.	1855–1867.	Means	Mean Cycle.	Rain Var.	Spot Var.	Year of Cycle.
	in.	in.	in.	in.	in.	in.	in.		
1	24.8	23.2	*23.8	20.3	23.0	—	—	—	—
2	22.1	*20.9	20.9	*28.5	23.1	22.8	− 2.8	− 37.2	1
3	15.3	21.0	26.6	24.9	22.0	23.8	− 1.8	− 22.8	2
4	32.6	25.2	31.5	24.3	28.4	26.3	+ 0.7	+ 4.4	3
5	25.2	33.0	22.8	25.9	26.7	28.0	+ 2.4	+ 33.0	4
6	**30.0**	**26.8**	**30.6**	**33.4**	**30.2**	**28.9**	**+ 3.3**	**+ 43.8**	**5**
7	33.2	31.0	22.2	28.6	28.8	28.4	+ 2.8	+ 32.9	6
8	24.5	23.4	21.3	33.9	25.8	26.1	+ 0.5	+ 14.3	7
9	23.2	25.5	22.8	25.6	24.3	25.2	− 0.4	− 2.9	8
10	*20.9	26.2	31.5	28.1	26.7	24.6	− 1.0	− 16.6	9
11	21.0	16.9	[1]21.8	23.6	20.8	23.1	− 2.5	− 24.7	10
12	25.2	*23.8	20.9	27.2	24.3	23.9	− 1.7	− 24.0	11
13	33.0	20.9	20.3	*31.0	26.3	—	—	—	—

An inspection of the above table will show that there is a remarkable coincidence between the rainfall and sun-spot variations—much more remarkable than at Madras. The years of maximum and minimum rainfall and sun-spot for the mean cycles coincide, and, on the whole, there is a regular gradation from minimum to maximum and from maximum to the next minimum.

The next table (the second half of the process for Edinburgh) gives almost equally remarkable results.

TABLE VI.—*Rainfall of Edinburgh* (*Minimum Years in Eighth Line*).

Year.	1826–1838.	1836–1848.	1849–1861.	1860–1872.	Means	Mean Cycle.	Rain Var.	Spot Var.	Year of Cycle.

3	25.2	31.0	22.8	33.9	28.2	27.8	+ 1.8	+ 15.9	2
4	*30.0	23.4	31.5	25.6	27.6	27.6	+ 1.6	+ 5.6	3
5	33.2	25.5	21.8	28.1	27.2	26.4	+ 0.4	− 5.4	4
6	24.5	26.2	20.9	23.6	23.8	24.1	− 1.9	− 20.4	5
7	23.2	16.9	20.3	27.2	21.9	23.4	− 2.6	− 36.3	6
8	**20.9**	**23.8**	**28.5**	**31.0**	**26.0**	**24.4**	**− 1.6**	**− 42.1**	**7**
9	21.0	20.9	24.9	28.6	23.8	24.6	− 1.4	− 28.6	8
10	25.2	26.6	24.3	22.2	24.6	25.2	− 0.8	+ 2.9	9
11	33.0	31.5	25.9	*22.1	28.1	26.8	+ 0.8	+ 35.3	10
12	*26.1	22.8	*33.4	23.2	26.4	28.2	+ 2.2	+ 48.9	11
13	31.0	*30.6	28.6	38.2	32.1	—	—	—	—

We find from the preceding table that the year of minimum rainfall was, on an average, the year immediately before the year of minimum sun-spot, and that the year of maximum sun-spot coincided with the year of maximum rainfall. Another coincidence is that the ratio of the rainfall to the sun-spots in the eleventh year of the "mean cycle" is nearly the same as the corresponding ratio in the first year of the cycle. Whether these relations are constant is another question ; in a case of

[1] Interpolated.

this kind we can scarcely venture to go beyond actual experience.

It would be easy to multiply similar examples and results of the method which I ventured to submit in my former paper to NATURE—a method the main object of which was to refer, as nearly as possible (without using the more laborious method of the harmonic analysis), the rainfalls of remote localities to the epochs of maximum and minimum sun-spots. I will, however, for the present only give, further, the results that have been obtained for the Paris rainfall from 1824 to 1867, and from 1816 to 1870.

TABLE VII.—*Rainfall of Paris* (*Maximum Years in Sixth Line*).

Year.	1824–1836.	1832–1844.	1843–1855.	1855–1867.	Means	Mean Cycle.	Rain Var.	Spot Var.	Year of Cycle.
	m.	m.	m.	m.	m	m.	m.		
1	572	456	*542	344	478	—	—	—	—
2	469	*503	571	*565	527	502	− 11	− 37·2	1
3	410	421	581	492	476	493	− 20	− 22·8	2
4	501	438	564	466	492	501	− 12	+ 4·4	3
5	585	611	430	545	543	541	+ 28	+ 33·0	4
6	**560**	**547**	**575**	**655**	**584**	**563**	**+ 50**	**+ 43·8**	**5**
7	573	542	597	458	543	554	+ 41	+ 32·9	6
8	529	580	563	516	547	522	+ 9	+ 14·3	7
9	456	455	469	426	452	487	− 26	− 2·9	8
10	*503	527	597	366	498	472	− 41	− 16·6	9
11	421	342	454	542	440	484	− 29	− 24·7	10
12	438	*542	614	644	559	520	+ 7	− 24·0	11
13	611	571	344	*565	523	—	—	—	—

The above table shows that, whether we take the "means" or the "mean cycle," the rainfall was greatest in the years of maximum sun-spot; that it was least in the ninth year of the "mean cycle;" and that, on the whole, the rainfall and sun-spots, notwithstanding some discrepancies, increased and decreased together.

The next table, in which the arrangement is inverted, gives similar results for Paris.

TABLE VIII.—*Rainfall of Paris* (*Minimum Years in Eighth Line*).

Year.	1816–1828.	1826–1838.	1836–1848.	1849–1861.	1860–1872.	Means	Mean Cycle.	Rain Var.	Spot Var.	Year of Cycle.

We see that the minimum rainfall occurred, on an average, in the year immediately preceding the year of minimum sun-spots, as at Edinburgh, but that the variation was not so regular.

As formerly remarked, the rainfalls of Edinburgh and Paris—especially that of Edinburgh—are more favourable to the theory than the rainfall of Madras.

Mr. Buchan considers the method which has now been sketched a new one, and, "as such, deserving of a careful examination as to how far it is applicable to the data submitted for discussion." This examination consists almost wholly in showing that by placing the maximum years in the same line or group the minimum years are spread over six out of thirteen groups, and that by placing the minimum years in the same group the maximum are also spread over six groups. Hence he concludes that this double arrangement is inferior to a single one in which the maximum and minimum years together are "compactly" spread over six out of eleven groups. But it seems to me that he has in great measure lost sight of what should be a main object of comparisons of sun-spots and rainfall, namely, the closest possible reference of the rainfall to the *epochs* of maximum and minimum sun-spots, and that however compact the arrangement he recommends may be considered, it is fundamentally objectionable. By placing the maximum and minimum years respectively in the *same* groups there is certainly a much greater chance of finding any connection that may exist between the two phenomena than by spreading them over six groups out of eleven.

How far the method defended by Mr. Buchan is applicable to the data will appear from the following table of the Madras rainfall, in which Dr. Hunter's arrangement is adopted. The maxima and minima years are marked with an asterisk.

TABLE IX.—*Rainfall of Madras* (*Maximum and Minimum Years in Six Groups*).

Year.	1811–1821.	1822–1832.	1833–1843.	1844–1854.	1855–1865.	1866–1876.	Means	Rain Var.	Spot Var.
	in.	in.	in.	in.	in.	in.	in.		
1	—	59·6	*37·1	65·4	32·3	51·4	49·2	+ 0·9	− 37·6
2	—	*26·6	39·0	38·1	*47·0	*24·4	35·0	− 13·3	− 35·0
3	45·1	33·7	41·5	79·8	52·9	41·4	49·1	+ 0·8	− 14·2
4	32·4	56·0	44·8	81·0	48·5	32·3	49·2	+ 0·9	+ 16·6
5	56·0	60·7	49·3	*54·8	55·1	*74·1	58·3	+ 10·0	+ 45·0
6	*41·2	88·4	52·3	39·8	*27·6	56·3	50·9	+ 2·6	+ 37·0
7	63·6	37·9	53·1	36·9	37·2	73·7	50·4	+ 2·1	+ 24·5
8	76·2	*36·9	58·6	64·3	38·2	51·8	54·3	+ 6·0	+ 11·0
9	36·3	32·4	58·3	72·7	54·6	62 9	52·9	+ 4·6	− 2·4
10	70·0	44·3	36·5	35·8	47·2	37·1	45·1	− 3·2	− 15·4
11	47·1	18·4	*50·3	43·2	41·6	21·5	37·0	− 11·3	− 29·2

The mean rainfall for the cycle is 48·3 inches. Now the mean rainfall for the fifth group is 58·3 inches, and the mean value of the sun-spots for the same group 45·0, which is the *maximum*. It is thus made to appear that, on an average, the maximum rainfall of Madras coincides with the maximum of sun-spots. But this is contrary to fact. We know, as a matter of observation (see Table III.), that the mean rainfall of Madras in the maximum years was not above the average, and yet the arrangement recommended by Mr. Buchan makes it *ten* inches *above* the average.

Applying the same arrangement to the rainfall of Edinburgh, we get the following results.

TABLE X.—*Rainfall of Edinburgh* (*Maximum and Minimum Years in Six Groups*).

Year.	1822–1832.	1833–1843.	1844–1854.	1855–1865.	Mean Rain.	Mean Spots.	Rain Var.	Spot Var.
	in.	in.	in.	in.	in.		in.	
1	26·1	*20·9	20·9	20·3	22·1	8·1	− 3·6	− 43·2
2	*30·3	21·0	26·6	*28·5	26·6	14·8	+ 0·9	− 36·5
3	24·8	25·2	31·5	24·9	26·6	37·4	+ 0·9	− 13·9
4	22·1	33·0	22·8	24·3	25·6	72·3	− 0·1	+ 21·0
5	15·3	*26·1	*30·6	25·9	24·5	92·4	− 1·2	+ 41·1
6	32·6	31·0	22·2	*33·4	29·8	86·4	+ 4·1	+ 35·1
7	25·2	23·4	21·3	28·6	24·6	73·2	− 1·1	+ 21·9
8	*30·0	25·5	22·8	33·9	28·0	63·3	+ 2·3	+ 12·0
9	33·2	26·2	31·5	25·6	29·1	50·9	+ 3·4	− 0·4
10	24·5	16·9	21·8	28·1	22·8	41·5	− 2·9	− 9·8
11	23·2	*23·8	20·9	23·6	22·9	23·9	− 2·8	− 27·4

In the above table the sun-spot maximum occurs in the 5th group, and the rainfall is made to be 1·2 inch below the mean; that is, according to this arrangement the people of Edinburgh are supposed to get *less* than their average allowance of rain in the maximum year. But according to the observations published by the Scottish Meteorological Society, that again is contrary to fact, for (see Table V.) the rainfall of Edinburgh is not 1·2 inch *below* the mean for the maximum years, but, taking the thirteen "means" five inches *above* it, and, taking the "mean cycle" 3 inches above it.

Which of the two methods, then, is the more applicable to the data for discussion?

Of all the methods, that of the harmonic analysis is doubtless the best. It enables us to see whether there is any parallelism, and if there is a cycle, what is its probable length with respect to the sun-spot cycle, the range of variation, the times of maximum and minimum, with their intervals, &c. I have applied this method to yearly values of the rainfalls, and of the levels of rivers of various countries, and have come to the conclusion that, notwithstanding all apparent irregularities, there is an intimate connection between sun-spots and rainfall.

If the rainfall generally was above its mean in the years of maximum sun-spot, and below it in the years of minimum sun-spot, we should get for the mean yearly rainfall of a number of stations the equation $\frac{S-s}{s'-S} = \frac{R-r}{r'-R}$, where S is the mean value of the sun-spots for the period examined, s the mean value of the spots when below S, s' their mean value when above S, and R, r, r' the corresponding values for the rain for the years from which S, s, and s' were obtained. This formula applied to the public observations of different countries shows that with very few exceptions the rainfall for the periods examined were above the average. The results for the mean rainfall of fifty-four stations in Great Britain, and thirty-four in America from 1824 to 1867 are as follows:—

$$\text{Great Britain} \ldots \ldots \begin{cases} \dfrac{S-s}{s'-S} = \dfrac{24{\cdot}9}{29{\cdot}8} = {\cdot}8356 \\ \dfrac{R-r}{r'-R} = \dfrac{+0{\cdot}75}{+0{\cdot}90} = {\cdot}8333 \end{cases}$$

$$\text{America} \ldots \ldots \ldots \begin{cases} \dfrac{S-s}{s'-S} = \dfrac{24{\cdot}9}{29{\cdot}8} = {\cdot}8356 \\ \dfrac{R-r}{r'-R} = \dfrac{+0{\cdot}94}{+1{\cdot}13} = {\cdot}8407 \end{cases}$$

In other words, the rainfall of fifty-four stations in Britain from 1824 to 1867 was 0·75 inch below the mean when the sun-spots were below their mean and 0·90 inch above it when the spots were in excess, and the corresponding values for America were 0·94 and 1·13 inch.

C. MELDRUM

Sun-spots and Weather

In NATURE, vol. xvii. p. 326, Dr. Balfour Stewart concludes an article with the following remark:—

"It is nearly, if not absolutely, impossible from observations already made, to tell whether the sun be hotter or colder as a whole when there are most spots on his surface. The sooner we get to know this the better for our problem."

The Bombay barometric observations appear to me to afford fairly conclusive evidence in favour of the sun being hottest about the time of maximum spotted area, and coldest when the spotted area is at its minimum.

It is well known that in Central Asia the annual variation of the barometric pressure is greater than in any other portion of the globe, and it is universally admitted that this variation is due to the great variation of temperature between summer and winter, the barometer being low when the temperature is high, and *vice versâ*. If, therefore, the absolute heat of the sun is subject to considerable variations, we ought to find the barometric pressure in Central Asia responding to those variations just as it does to the annual variations of temperature; in other words, the summer barometric minimum should be lowest in those years when the sun is hottest, and the winter maximum should be highest in those years when the sun is coldest.

Similar results should be obtainable from the barometric records of any station where the annual variation of pressure is considerable and of the same character as in Central Asia. Bombay is such a station, and one where cyclonic disturbances are less frequent and violent than at most other Indian coast stations. I give below the mean barometric pressure at Bombay for the summer and winter half-years from 1847 to 1877:—

Mean Barometric Pressure at Bombay.

The winter means correspond in time to the beginning of each year, the summer means to the middle of each year. Taking the mean of each pair of winter means, we obtain a new set of numbers which correspond to the middle of each year, and which give a somewhat smoother curve than the original numbers, and performing a similar operation twice upon the summer means, we obtain a similarly smoothed set of numbers also corresponding to the middle of each year. These two sets of smoothed numbers, and their means, are given below, and graphically represented by the accompanying curves, along with the inverted sun-spot curve.

—	1848.	1849.	1850.	1851.	1852.	1853.	1854.	1855.	1856.	1857.	1858.	1859.	1860.	1861.	1862.

	29+	29+	29+	29+	29+	29+	29+	29+	29+	29+	29+	29+	29+	29+	29+
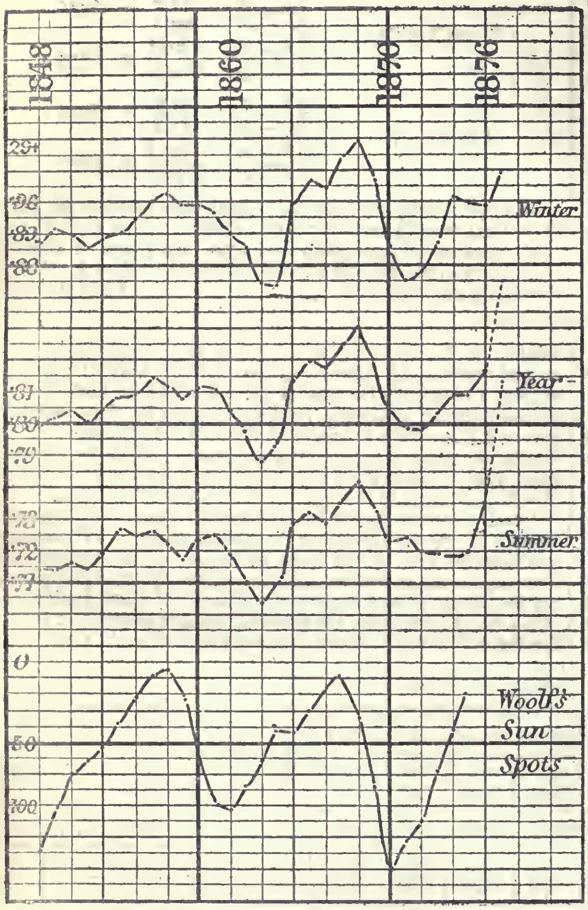
Winter	·873	·898	·907	·904	·915	·919	·908	·887	·875	·878	·887	·901	·899	·898	·909
Summer	·712	·729	·732	·729	·735	·742	·733	·724	·724	·720	·719	·718	·719	·735	[·773]
Year	·792	·813	·819	·816	·825	·830	·820	·805	·799	·799	·803	·809	·809	·816	[·845]

It will be seen that there is a remarkable degree of resemblance in the progression of these phenomena from year to year, but that the barometric curve "lags behind" the sun-spot curve, particularly in the years of maximum sun-spots.



The winter curve is more regular than the summer one, probably because the weather generally in India is more settled in the winter than in the summer, but on the whole the two curves support each other in showing a low pressure about the time of sun-spot maximum, and a high pressure at the time of sun-spot minimum. We may therefore conclude that the sun is hottest about the time when the spots are at a maximum, and coldest when they are at a minimum.

The range of the variation of the year by mean pressure from the minimum of 1862 to the maximum of 1868, is ·042 of an inch, and the mean range of the barometer from January to July is ·291, from which it appears that the variations of pressure produced by absolute variations of the sun's heat are, in comparison with the usual seasonal changes, by no means insignificant.

These results appear to harmonise well with the decennial variations of the rainfall in India, and to throw light upon the inverse variation (compared with the sun-spots) of the winter rainfall of Northern India. Mr. Archibald has attempted to explain this latter phenomenon on the assumption that the sun is coldest when it is most spotted, but the inverse winter variation of the rainfall of Northern India, as well as the direct variation at Madras, Bombay, Trevandrum, and elsewhere, appear to me to follow more naturally from the contrary view; for if the winter rainfall in Northern India is really due to the cold of winter we should expect it to be greatest when the sun is coldest, just as the summer rainfall is expected to be greatest when the sun is hottest. FRED. CHAMBERS

Bombay, August 23

The Norwegian Arctic Expedition

THE *Vöringen*, Capt. Wille, returned to Christiania on the 10th, from Spitzbergen, after a most successful cruise. No less than 375 stations have been thus explored by sounding, dredging, and trawling during the last three summers; and the *Morgenbladet* reminds us that only 354 of such stations were recorded in the notice of the *Challenger* expedition. The number of stations in the *Porcupine* cruises of 1869 and 1870 was 148.

Prof. G. O. Sars informs me that in every department of zoology a vast amount of material was procured in his last cruise, and that especially the Mollusca are abundantly represented, not only by magnificent specimens of rare Arctic species, such as *Fusus kroyeri* and *F.* (*Neptunea*) *deformis*, but also by several interesting new forms. He adds that the conchological collection from this cruise is indeed much richer than both of those made in his former two cruises. Herr Friele will work out all the Mollusca.

I cannot omit expressing my admiration of the recent work of Prof. G. O. Sars, entitled "Mollusca Regionis Arcticæ Norvegiæ." His descriptions are excellent, and his figures (all by his own hand, and autographed) are inimitable. The work contains 466 pages and 52 plates, besides a chart.

Ware Priory, Herts, September 23 J. GWYN JEFFREYS

Albinism in Birds

WHEN I was forming the Government Central Museum at Madras, an albino crow was brought to me, which was stuffed and placed in the museum. It was mentioned to me at the same time that there is a colony of albino crows at a part of the Malabar coast, but I have never been able to verify the statement. That district is daily becoming more frequented by Europeans, and some of them may soon be in a position to ascertain how far the report was correct. EDWARD BALFOUR

2, Oxford Square, September 19

As Mr. Page says, in NATURE (vol. xviii. p. 540), he has only heard of one white swallow, it may be interesting to him and your readers to learn that in the Newcastle Museum there is a specimen, also white specimens of the rook, pheasant, curlew, sparrow, and starling; in the same collection will also be found a "pale rose" coloured specimen of the bullfinch.

Newcastle-upon-Tyne, September 20 WM. LYALL

"Hearing of Insects"

I AM able to confirm the accounts given by Mr. Simson in your last number as to the probability of the hearing of insects. When travelling on the River Magdalena, New Granada, in 1861, the mode of which is by a long boat, arched over with bamboo, on which the sailors (bogas) passing from one extremity to the other, propel it with long poles, hugging the river bank, accompanied with wild cries and execrations, I observed on several occasions that these cries suddenly ceased, a dead silence following, and on inquiring the cause they pointed to nests high up in the trees, whispering the word vispa (wasp). As the bogas pursue their avocations in a state of semi-nudity, they have the greatest dread of these insects, fearing to speak aloud, as their only alternative if attacked by them is to plunge into the stream, where alligators abound. The wasp is long, slender, and black in colour.

117, Cromwell Road, S.W., Sept. 21 W. L. DUDLEY

The Meteor Shower of Andromedes I.

MR. GREG's meteor radiant (No. 103 of his 1876 catalogue) at R.A. 7°, Dec. 33° N., for July 21 to August, really consists of two well-defined showers near α Andromedæ. The meteors are quite distinct, and, moreover, there is a difference of 10° in declination. My observations since 1873 indicate two positions as below:—

I. July 6 to August 16, 6° + 37°	60 very swift streak-leaving meteors.
II. July 6 to August 11, 3° + 27°	23 slow, bright, trained meteors.

Schiaparelli and Zezioli, Greg and Herschel, and Tupman, found the former some years ago, and Denza gives the latter at 2° + 29° August 8–13. Mr. Greg averages these with several others (including one by Schmidt at 7° + 30°, and another by Heis at 11° + 30°, both for August) and finds a centre at 7° + 33° for the whole. There is no doubt, however, that there are *two* conspicuous contemporary radiants of entirely

different meteors. This year, on August 10, in bright moonlight, I traced five meteors from $6° + 37°$, and the epoch and place fall near Comet II. 1780, August 14, $3\frac{1}{2}° + 38\frac{1}{2}°$, but the comet was only visible for three days after its discovery by Montaigne and others on November 28, 1780, and hence the orbit is not likely to have been exactly determined. At the nodal passage the comet's orbit lies far within the orbit of the earth, so that an encounter of the earth with the comet-particles is only possible on the thesis of Weiss and Schiaparelli that "some part of the cometary materials repelled from its proper orbit by the sun in the form of the tail or other luminous appendage emitted by the comet near its perihelion passage extends to such a distance in its orbital plane as to intersect the orbit of the earth" (see B.A. *Report*, 1873, pp. 401–2).

Ashleydown, Bristol, September 16 W. F. DENNING

The Zoological Record

IN the third number of vol. iii. of the *Niederländisches Archiv für Zoologie* (Leiden: E. T. Brill), I published in German a "Catalogue Raisonné" of zoological works and papers that appeared in the Netherlands during 1875 and 1876. You noticed the appearance of this paper in your "Notes" (NATURE, vol. xvi. p. 112).

The principal reason of my publishing this bibliography was my wish to make known in other countries what is done in the Netherlands in the zoological department. For the same purpose, about the end of May, 1877, I sent a copy of my paper to the *Zoological Record* and addressed it "Solely to the Editor of the *Zoological Record*, care of Mr. Van Voorst, 1, Paternoster Row, London."

Afterwards studying vol. xii. and xiii. of the said "Record," I found that about twenty of the papers recorded in my catalogue were not mentioned in these volumes. Of course this might have been occasioned by the unimportance of these twenty unlucky papers; but conscientiously comparing their value with that of the other sixty of my bibliography, and as far as possible in general with the papers mentioned in the *Record* I got the conviction that this could not be the reason.

I feel a great deal of admiration, and at the same time of gratitude for the immense amount of work done by the contributors of the *Record*, and I quite agree with you (NATURE, vol. xviii. p. 485) that it would be to the everlasting disgrace of zoologists (not only of your tongue, but of all tongues) if its existence should be prematurely brought to a close. But only when I find in the *Record* as much completeness as possible, the use of it will spare me the endless trouble of looking for every detail over the totality of zoological literature.

Now I don't believe that in the case mentioned here (to secure this completeness) much care has been taken.

September 19 P. P. C. HOEK

Earth Pillars

SHOULD you deem the following of sufficient interest, will you kindly insert it in NATURE?

A few days since I saw an interesting example of minute earth-pillars on the shore of the Hecht Sea, above Kiefersfelden, Inn Thal. In a cove to the north the beach for many yards formed a perfect forest of little pillars, whose height ranged from a quarter to three-quarters of an inch. On the top of most lay a small stone, a fragment of wood or shell; but some, which had lost their coverings, were wearing away. The shell fragments (from a Unio, I fancy) seemed to form the most complete protection, and these often fitted the pillars like helmets; in fact, it required no great stretch of the imagination to fancy the whole a marching army, and the jutting wood fragments spears.

South Tyrol is by no means the only place in this country where earth-pillars occur, though the Bozen pillars are probably the finest. Amongst others in North Tyrol there is a very interesting example of large earth-pillars on the Brenner railway, between Innsbruck and Patsch, on the right—going south. JAMES H. MIDGLEY

Brixlegg am Inn, Tyrol, September 17, 1878

Indian Building Timber

IN NATURE, vol. xviii. p. 317, it is stated "much or most of the wood used in Peking in building houses, temples, and palaces is said to come from Corea;" it is further remarked editorially, "we think, however, our contemporary is in error in stating, without qualification, that 'the great wooden masts which support the noble temples and gatehouses of the Imperial City of Peking (all enormous, beautiful, and enduring spars) come from Corea.'"

Having had some experience in the timber and timber-trees of Burma I am inclined to the opinion that this valuable timber "nan-mu" therein referred to will prove to be identical with the wood used for the same purposes generally over Burma. The wood is called in Lower Burma "Pyenkadoo," it has a wide distribution under a variety of names, according to the different provincial dialects of the districts it is found in. Its great length of bole without branches, the different sizes at which it can be obtained renders it from its great durability, readiness to polish, and its variegated and coloured grain (brown mahogany colour) most suitable for the supports or pillars of "kyoings," or temples. It belongs to the natural order Leguminoseæ, specific name *Ingá xylocarpa*.

Besides this there are several other woods highly esteemed by the Burmese for durability, and these chiefly are found amongst the Cassias and Dalbergias.

Inga xylocarpa has great toughness—a piece of three feet long by one inch square I find stood a breaking weight of 1,153 pounds; its specific gravity is nearly double that of teak and it does not float.

The objection to the introduction of the different ornamental and useful timbers of Burma is their toughness, hardness to work, and hence increased labour and wear of tools.

Whitby R. BENSON

[With reference to the question of the identity of the wood of the "nan-muh" tree with that of *Inga xylocarpa* we may point out that from material received at Kew the former has been referred to a Lauraceous tree, probably *Phœbe pallida*. From comparison of the two woods microscopically they present something in common, the annual rings, however, are much more apparent in the "nan-muh" than in the "Pyenkadoo." This latter is of a dark reddish brown, extremely heavy, as described by Col. Benson, while the nan-muh is of a dull umber colour and much lighter in weight.—ED.]

OUR ASTRONOMICAL COLUMN

THE INTRA-MERCURIAL PLANET.—The particulars of Mr. Lewis Swift's observations during the totality of the recent eclipse, given in his letter which appeared in NATURE last week, are satisfactory so far as they afford independent testimony to the existence of an unknown body in the vicinity of the star θ Cancri, or in the locality where Prof. Watson, a few minutes previously, had observed an object which he considers to have been an intra-Mercurial planet. In other respects Mr. Swift's letter is indefinite and contradictory in itself. He tells us that he observed two red stars "with large, round, and equally bright discs," estimating the distance between them at about 7′ or 8′; and, one of the objects being identified with θ Cancri, he intimates that the proximity of the other to this star enabled him to estimate its position with great exactness, especially in declination. But in a subsequent paragraph, where the place of the star is adopted from the Astronomer-Royal, the unknown object is fixed to a position which makes its distance from θ Cancri 30′, or four times as great as mentioned previously. The place of the supposed planet, according to Prof. Watson, was, as stated last week, in right ascension 8h. 27m. 24s., and declination 18° 16′ N.; and as the apparent place of the star at the time was in right ascension 8h. 24m. 39·9s., and declination 18° 30′ 19″, the distance between the two was 42′, on an angle at the star, of 110°. With regard to Mr. Swift's concluding observation as to the position of the presumed planet in its orbit, it is evident that, to present a round or nearly round disc, it must have been situate, as Prof. Watson infers, in the superior part of the orbit, and being to the west of the sun, would be approaching superior conjunction.

Prof. Watson states that the magnitude of the object in question was 4 to $4\frac{1}{2}$, and that of the second unknown star, which he alone appears to have observed, was $3\frac{1}{2}$, and adds, "they were probably really brighter, because

the illumination of the sky was not considered in the estimates." Before he entered upon the reduction of his observations, he had thought the second object might be ζ Cancri (though surprised to find it so bright) because he did not see that star—a well-known double star, components $5\frac{1}{2}$ and $6\frac{1}{2}$,—a gust of wind which occurred just before the end of totality having possibly disturbed the telescope. Yet, the circumstance of his not having remarked ζ Cancri would be accounted for by his statement that he did not sweep further than the second object, which his reading places in right ascension 8h. 9m. 24s., declination 18° 3′, and which he believes to be correct—the sun coming out immediately afterwards, and of course putting an instantaneous termination to his observations.

VARIABLE STARS.—The following are the Greenwich times of geocentric minima of Algol and S Cancri in the last quarter of the present year, which fall between dusk and 13h. M.T.

The maximum of Mira Ceti occurs on October 11, and the minimum of χ Cygni on October 26, according to Prof. Schönfeld.

THE METEOR OF DECEMBER 24, 1873.—Mr. Cleveland Abbe, Director of the Observatory of Cincinnati, sends us a discussion of the observations of a remarkable meteor seen on Christmas Eve, 1873, to which the attention of the Washington Philosophical Society had been particularly directed soon after its occurrence, and, on the suggestion of the late secretary of the Smithsonian Institution, a committee formed with the view of collecting and discussing observations. Though about fifty accounts of the appearance of the meteor were thus brought together, they have only sufficed to give a general idea of its track and altitude. Nearly all the observers describe it as equalling the full moon in brightness, with conical form moving base forward, but not followed as in so many cases, by any regular train; colour bright yellow, sparks or flames of red and blue proceeding from it. Mr. Abbe finds that it "entered the earth's atmosphere at some point vertically above the northern part of the State of Delaware, so that its apparent altitude, as seen at Danbury, Conn., was 30°, and at Washington, D.C., about 45°," whence he concludes its real altitude above the earth's surface to have been about ninety miles. Its after-course was downward to beyond Fairfax county, and at its nearest approach to the earth it was distant twenty miles. Its entire visible path of about 120 miles was described in from three to five seconds. An explosion occurred at a distance of about thirty miles from Washington, where the meteor was observed, amongst others, by Profs. Newcomb, Hilgard, and Holden.

MR. THOMAS GRUBB, F.R.S.

WE regret to announce the death of Mr. Thomas Grubb, F.R.S., and we cannot do so without referring to his marked talents and the important service he has rendered to science.

Mr. Grubb was originally intended for a mercantile career, but his natural tastes proved too strong to allow him to continue in the life he had begun. He became a mechanical engineer, and soon his workshops became known not only for excellent workmanship but still more for marked originality of conception in design. His *chef-d'œuvre* in both these respects is probably the machinery for engraving, printing, and numbering the notes of the Bank of Ireland.

Whilst Mr. Grubb's workshops were rising in reputation, he was quietly and steadily developing marked powers as a practical optician. During the construction of the great 6-feet equatorial at Parsonstown, the late Lord Rosse frequently acknowledges his obligations to Mr. Grubb for valuable suggestions. The system of levers on which Lord Rosse supported his specula, to avoid flexure, was of Mr. Grubb's invention. Of his chief scientific works we may mention :—

1. The equipment of nearly forty British magnetic stations under the direction of Provost Loyd.
2. A 15-inch reflecting telescope equatorially mounted at the Armagh Observatory.
3. The equatoreals of the Markree and Dunsink Observatories—refractors of 13 and 12 inches aperture respectively. And lastly, the great Melbourne telescope of 4 feet aperture, equatorially mounted, and driven by clockwork. After this last achievement Mr. Grubb retired from business life, succeeded by his son, Mr. Howard Grubb.

Such works as the 15-inch refractors in the observatories of Lord Lindsay and Dr. Huggins, and the great refractor of 27 inches aperture now in course of construction for Vienna show that the son is no unworthy representative of the father.

Mr. Thomas Grubb was elected a Fellow of the Royal Society of London in 1864, in recognition of his successful completion of the great Melbourne telescope, and of his other successful labours in the cause of science. He was also a member of the Royal Irish Academy. He died on the 19th instant at his residence in Dublin, and leaves to mourn his loss a large circle of friends whom his kindly genial manners and ever interesting conversation had drawn round him.

MR. THOMAS BELT, F.G.S.

THE scientific world will hear with regret the recent death of the well-known naturalist and geologist, Mr. Thomas Belt, F.G.S., which has just been telegraphed from Colorado. It is believed to have been caused by mountain fever. Elected a Fellow of the Geological Society in 1866, the geological world owes to him the division of the Lingula flags into Maentwrog, Ffestiniog, and Dolgelly flags, proposed in 1867. In 1874 appeared his well-known and deservedly popular "Naturalist in Nicaragua," in which he showed how his professional avocations as an engineer had lent keenness to his observing faculties, and how an acute reasoner can utilise his observations. The work conveyed much information on protective mimicry, plant-fertilisation, sexual selection, and the other collateral issues of the theory of evolution. It contained the first sketch of those views on glacial geology which were the most prominent subject of the author's study for the rest of his life. These views were given in considerable detail in the *Geological Magazine* for April, 1874, and were well expounded by Mr. Henry Woodward, F.R.S., in his presidential address of that year to the Geologists' Association. Mr. Belt skilfully answered his opponents in NATURE, vol. x., his controversial speaking and writing being always marked by a candour and temper which, if it did not carry conviction, could not fail to elicit admiration from perfect strangers and mere spectators. In November, 1875, he read a paper to the Geological Society "On the Drift of Devon and Cornwall" (*Quart. Jour. Geol. Soc.*, vol. xxxii.), and another "On the Steppes of Southern Russia" (*Quart. Jour. Geol. Soc.*, vol. xxxiii.), in June, 1877. He also contributed various papers to the *Quarterly Journal of Science*, amongst others one "On the Loess of the Rhine and the Danube," in January, 1877, and one "On the Glacial Period in the Southern Hemisphere," in July, 1877.

ON THE NATURE OF VIBRATORY MOTIONS[1]

On the Nature of Sound

SOUND is the sensation peculiar to the ear. This sensation is caused by rapidly-succeeding to-and-fro motions of the air, which touches the outside surface of the drum-skin of the ear. These to-and-fro motions may be given to the air by a distant body, like a string of a violin. The string moves to and fro, that is, it *vibrates.* These vibrations of the string act on the bridge of the violin, which rests on the belly or sounding-board of the instrument. The surface of the sounding-board is thus set trembling, and these tremors, or vibrations, spread through the air in all directions around the instrument, somewhat in the manner that water-waves spread around the place where a stone has been dropped into a quiet pond. These tremors of the air, however, are not sound, but the cause of sound. Sound, as we have said, is a *sensation;* but, as the cause of this sensation is always vibration, we call those vibrations which give this sensation *sonorous vibrations.* Thus, if we examine attentively the vibrating string of the violin, we shall see that it looks like a shadowy spindle, showing that the string swings quickly to and fro; but, on closing the ears, the sensation of sound disappears, and there remains to us only the sight of the quick to-and-fro motion which, the moment before, caused the sound.

Behind the drum-skin of the ear is a jointed chain of three little bones. The one, H of Fig. 1, attached to the

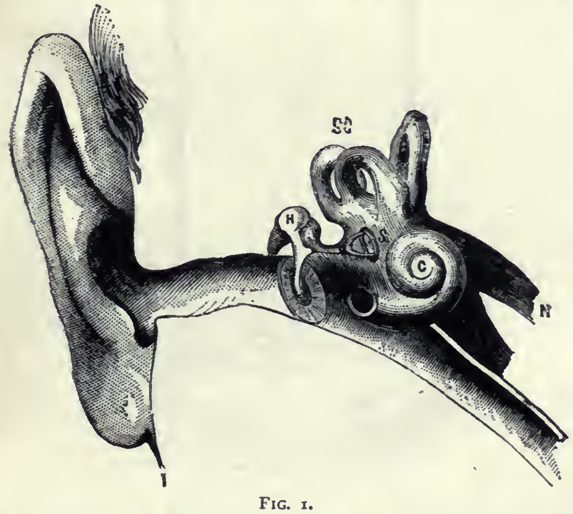

FIG. 1.

drum-skin, is called the *hammer;* the next, A, is called the *anvil;* the third, S, has the exact form of a stirrup, and is called the *stirrup-bone.* This last bone of the chain is attached to an oval membrane, which is a little larger than the foot of the stirrup. This oval membrane closes a hole opening into the cavity forming the *inner ear;* a cavity tunnelled out of the hardest bone of the head, and having a very complex form. The oval hole just spoken of opens into a globular portion of the cavity known as the vestibule, and from this lead three semicircular canals, S C, and also a cavity, C, of such a marked resemblance to a snail's shell that it is called *cochlea,* the Latin word for that object. The cavity of the inner ear is filled with a liquid, in which spread out the delicate fibres of the auditory nerve.

Let us consider how this wonderful little instrument acts when sonorous vibrations reach it. Imagine the violin-string vibrating 500 times in one second. The sounding-board also makes 500 vibrations in a second. The air touching the violin is set trembling with 500 tremors a second, and these tremors speed with a velocity of 1,100 feet in a second in all directions through the surrounding air. They soon reach the drum-skin of the ear. The latter, being elastic, moves in and out with the air which touches it. Then this membrane, in its turn, pushes and pulls the little ear-bones 500 times in a second. The last bone, the little stirrup, finally receives the vibrations sent from the violin-string, and sends them into the fluid of the inner ear, where they shake the fibres of the auditory nerve 500 times in a second. These tremors of the nerve—how we know not—so affect the brain that we have the sensation which we call sound. The description we have just given is not that of a picture created by the imagination, but is an account of what really exists, and of what can actually be seen by the aid of the proper instruments.

A body may vibrate more or less frequently in a second; it may swing over a greater or less space; and it may have several minute tremors while it makes its main swing. These differences in vibrations make sounds higher or lower in pitch, loud or soft, simple or compound. It is easy to say all this, but really to understand it, one must make experiments and discover these facts for himself.

On the Nature of Vibratory Motions

The character of a sound depends on the nature of the vibrations which cause it, therefore our first experiments will be with vibrations which are so slow that we can study the nature of these peculiar motions. These experiments will be followed by others on vibrations of the same kind, only differing in this—that they are so rapid and frequent that they cause sounds. A correct knowledge of the nature of these motions lies at the foundation of a clear understanding of the nature of sound. We hope that the student will make these experiments with care, and keenly observe them.

Experiment 1.—At the toy-shops you can buy for a few pence a wooden ball having a piece of elastic rubber fastened to it. Take out the elastic and lay it aside, as we shall need it in another experiment. Get a piece of fine brass wire, about 2 feet (61 centimetres) long, and fasten it to the ball. The weight of the ball should pull the wire straight, and, if it does not, a finer wire must be used. Hold the end of the wire in the left hand, and with the right hand draw the ball to one side. Let it go, and it will swing backward and forward like the pendulum of a clock. This kind of movement we call a *pendulous or transverse vibration.*

Experiment 2.—Cut out a narrow triangle of paper, 4 inches (10 centimetres) long, and paste it to the bottom of the ball. Twist the wire which supports the ball by turning the latter half round, and watch the paper pointer as it swings first one way and then the other. Here we have another kind of vibration, a motion caused by the twisting and untwisting of the wire. Such a motion is called a *torsional vibration.*

Experiment 3.—Take off the wire and the paper, and put the elastic on the ball. Hold the end of the elastic in one hand, and with the other pull the ball gently downward, then let it go. It vibrates up and down in the direction of the length of the elastic. Hence we call this kind of motion a *longitudinal vibration.*

These experiments show us the three kinds of vibrations, transverse, torsional, and longitudinal. They differ in direction, but all have the same manner of moving; for the different kinds of vibration, transverse, longitudinal, and torsional, go through motions with the same changes in velocity as take place in the swings of an ordinary pendulum. These vibrations all start from a position of momentary rest. The motion begins slowly, and gets faster and faster till the body gains the position it naturally has when it is at rest—at this point it has its

[1] From a forthcoming work on "Sound: a Series of Simple, Entertaining, and Inexpensive Experiments in the Phenomena of Sound, for the Use of Students of every Age." By Alfred Marshall Mayer, Professor of Physics in the Stevens Institute of Technology. Communicated by the author.

greatest velocity. Passing this point, it goes slower and slower till it again comes momentarily to rest, and then begins its backward motion, and repeats again the same changes in velocity.

It is now necessary that the student should gain clear ideas of the nature of this pendulous motion. It is the cause of sound. It exists throughout all the air in which a sound may be perceived, and, by the changes in the number, extent of swing, and combinations of these pendular motions, all the changes of pitch, of intensity, and of quality of sound are produced. Therefore the knowledge which we now desire to give the reader lies at the very foundation of a correct understanding of the subject of this book.

An experiment is the key to this knowledge. It is the experiment with

The Conical Pendulum

An ordinary pendulum changes its speed during its swings right and left exactly as a ball *appears* to change its speed when this ball revolves with a uniform speed in a circle, and we look at it along a line of sight which is in the plane of the circle.

Experiment 4.—Let one take the ball and wire to the farther end of the room, and by a slight circular motion of the end of the wire he must cause the ball to revolve in a circle. Soon the ball gets into a uniform speed around the circle, and then it forms what is called a conical pendulum; a kind of pendulum sometimes used in clocks. Now stoop down till your eye is on a level with the ball. This you will know by the ball appearing

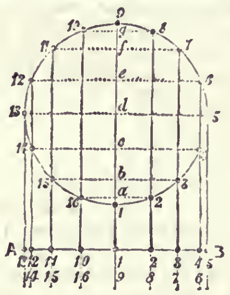

FIG. 2.

to move from side to side *in a straight line*. Study this motion carefully. It reproduces exactly the motion of an ordinary pendulum of the same length as that of the conical pendulum. From this it follows that the greatest speed reached during the swing of an ordinary pendulum just equals the uniform speed of the conical pendulum. That the apparent motion you are observing is really that of an ordinary pendulum you will soon prove for yourself to your entire satisfaction; and here let me say that one principle or fundamental fact seen in an experiment and patiently reflected on is worth a chapter of verbal descriptions of the same experiment.

Suppose that the ball goes round the circle of Fig. 2 in two seconds; then, as the circumference is divided into sixteen equal parts, the ball moves from 1 to 2, or from 2 to 3, or from 3 to 4, and so on in one-eighth of a second. But to the observer who looks at this motion in the direction of the plane of the paper the ball *appears* to go from 1 to 2, from 2 to 3, from 3 to 4, &c., on a line A B, while it really goes from 1 to 2, from 2 to 3, from 3 to 4, &c., in the circle. The ball when at 1 is passing directly across the line of sight, and, therefore, appears with its greatest velocity; but when it is in the circle at 5 it is going away from the observer, and when at 13 it is coming toward him, and, therefore, although the ball is really moving with its regular speed when at 5 and 13, yet it appears when at these points momentarily at rest. From a comparison of the similarly numbered positions of the ball in the circle and on the line A B, it is evident that the ball appears to go from A to B and from B back to A in the time it takes to go from 13 round the whole circle to 13 again. That is the ball appears to vibrate from A to B in the time of one second, in which time it really has gone just half round the circle. A comparison of the unequal lengths 13 to 12, 12 to 11, 11 to 10, &c., on the line A B, over which the ball goes in equal times, gives the student a clear idea of the varying velocity of a swinging pendulum.

Fig. 3 represents an upright frame of wood standing on a platform, and supporting a weight that hangs by a cord. A A is a flat board about 2 feet (61 centimetres) long and 14 inches (35·5 centimetres) wide. B B are two uprights so high that the distance from the under side of the cross-beam C to the platform A A is exactly 41$\frac{1}{10}$ inches (1 metre and 45 millimetres). The cross-beam C is 18 inches (45·7 centimetres) long. At D is a wooden post standing upright on the platform. Get a lead disk, or bob, 3$\frac{3}{16}$ inches (8 centimetres) in diameter, and $\frac{5}{8}$ inch (16 millimetres) thick. In the centre of this is a hole 1 inch (25 millimetres) in diameter. This disk may easily be cast in sand from a wooden pattern. At the tinner's we may have made a little tin cone 1$\frac{3}{16}$ inch (30

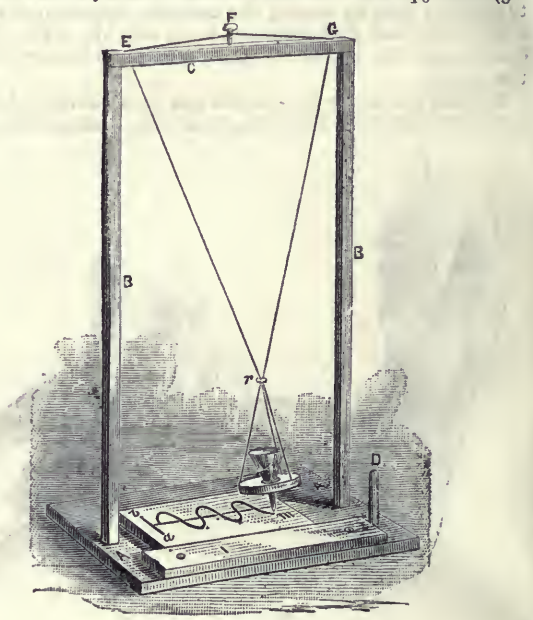

FIG. 3.

millimetres) wide at top, and 2¼ inches (57 millimetres) deep, and drawn to a fine point. Carefully file off the point till a hole is made in the tip of the cone of about $\frac{1}{16}$ inch in diameter. Place the tin cone in the hole in the lead disk, and keep it in place by stuffing wax around it. A glass funnel, as shown in the figure, may be used instead of the tin cone. With an awl drill three small holes through the upper edge of the bob at equal distances from each other. To mount the pendulum, we need about 9 feet (271·5 centimetres) of fine strong cord, like trout-line. Take three more pieces of this cord, each 10 inches (25·4 centimetres) long, and draw one through each of the holes in the lead-bob and knot it there, and then draw them together and knot them evenly together above the bob, as shown in the figure. On the cross-bar, at the top of the frame, is a wooden peg shaped like the keys used in a violin. This is inserted in a hole in the bar—at F in the figure. Having done this, fasten one end of the piece of trout-line to the three cords of the bob, and pass the other end upward through the hole marked E; then pass it through the hole in the key F; turn the key round several times; then pass the cord through the

hole at G, to the bob, and fasten it there to the cords. Then get a small bit of copper wire and bend it once round the two cords just above the knot, as at *r* in the figure. This wire ring, and the upright post at the side of the platform, we do not need at present, but they will be used in future experiments with this pendulum.

Tack on the platform A A a strip of wood I. This serves as a guide, along which we can slide the small board *m*, on which is tacked a piece of paper.

Experiment 5.—Fill the funnel with sand, and, while the pendulum is stationary, steadily slide the board under it. The running sand will be laid along L M, Fig. 4, in a straight line. If the board was slid under the sand during exactly two seconds of time, then the length of this line may stand for two seconds, and one-half of it may stand for one second, and so on. Thus, we see how time may be recorded in the length of a line.

Brush off the heaps of sand at the ends of the line, and

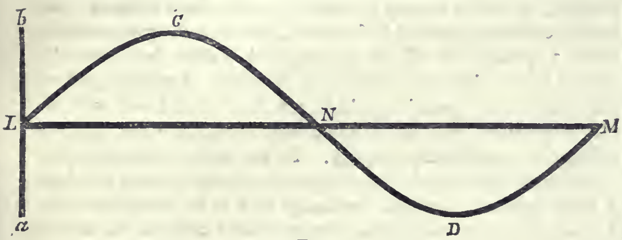

FIG. 4.

bring the left-hand end of the sand-line directly under the point of the funnel, when the latter is at rest. Draw the lead bob to one side, to a point which is at right angles to the length of the line, and let it go. It swings to and fro, and leaves a track of sand, *a b*, which is at right angles to the line L M, Fig. 4.

Suppose that the pendulum goes from *a* to *b*, or from *b* to *a*, in one second, and that, while the point of the funnel is just over L, we slide the board so that, in two seconds, the end M of the line L M comes under the point of the funnel. In this case the sand will be strewed by the pendulum to and fro, while the paper moves under it through the distance L M. The result is that the sand appears on the paper in a beautiful curve L C N D M. Half of this curve is on one side of L M, the other half on the opposite side of this line.

The experimenter may find it difficult to begin moving the paper at the very instant that the mouth of the funnel

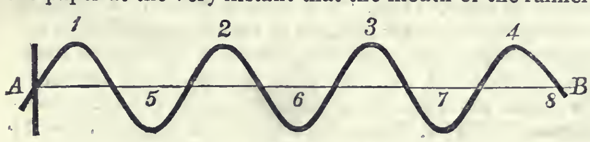

FIG. 5.

is over L; but, after several trials, he will succeed in doing this. Also, he need not keep the two sand-lines, L M and *a b*, on paper during these trials; he may as well use their traces, made by drawing a sharply-pointed pencil through them on to the paper.

By having a longer board, or by sliding the board slowly under the pendulum, a trace with many waves in it may be formed, as in Fig. 5.

As the sand-pendulum swung just like an ordinary pendulum when it made the wavy lines of Figs. 4 and 5, it follows that these lines must be peculiar to the motion of a pendulum, and may serve to distinguish it. If so, this curve must have some sort of connection with the motion of the conical pendulum, described in Experiment 4. This is so, and this connection will be found out by an attentive study of Fig. 6.

In this figure we again see a wavy curve, under the same circular figure which we used in explaining how the motion of an ordinary pendulum may be obtained from the motion of a conical pendulum. This wavy curve is made directly from measures on the circular figure, and certainly bears a striking resemblance to the wavy trace made by the sand-pendulum in Experiment 5. You will soon see that to prove that these two curves are precisely the same is to prove that the apparent motion of the conical pendulum is exactly like the motion of the ordinary pendulum.

The wavy line of Fig. 6 is thus formed:—The dots on A B, as already explained, show the apparent places of the ball on this line, when the ball really is at the points correspondingly numbered on the circumference of the circle. Without proof, we stated that this apparent motion on the line A B was exactly like the motion of a pendulum. This we must now prove. The line L M is equal to the circumference of the circle stretched out. It is made thus:—We take in a pair of dividers the distance I to 2, or 2 to 3, &c., from the circle, and step this distance off sixteen times on the line L M; hence L M equals the length of the circumference of the circle. *In time* this length stands for two seconds, for the ball in Experiment 4 took two seconds to go round the circle. This same length, you will also observe, was made in the same time as the sand-line L M was made in Experiment 5. In Fig. 6 the length L M, of two seconds, is divided into sixteen parts; hence each of them equals one-eighth of a second, just as the same lengths in the circle equal eighths of a second. Thus the line L M of Fig. 6, as far as a record of time is concerned, is exactly like the sand-line L M of Experiment 5, and the line A B of Fig. 6, in which the ball appeared to move, is like the line *a b* of Fig. 4, along which the sand-pendulum swung.

Now take the lengths from I to 2, I to 3, I to 4, I to 5, and so on, from the line A B of Fig. 6, and place these lengths at right angles to the line L M at the points I, 2, 3, 4, 5, and so on; by doing so, we actually take the distances at which the ball appeared from I (its place of greatest velocity), and transfer them to L M; therefore, these distances correspond to the distances from L M, Fig. 4, to which the sand-pendulum had swung at the end of the times marked on L M of Fig. 6.

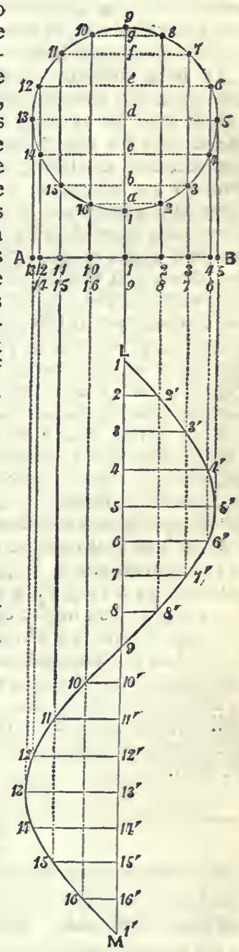

FIG. 6.

Join the ends of all these lines, 2 2′, 3 3′, 4 4′, &c., by drawing a curve through them, and we have the wavy line of Fig. 6.

This curve evidently corresponds to the curve L C N D M of Fig. 4 made by the sand-pendulum; and it must be evident that, if this curve of Fig. 6 is *exactly* like the curve traced by the sand-pendulum in Experiment 7, it follows that the *apparent* motion of the conical pendulum, as seen in the plane in which it revolves, is exactly like the *real* motion of an ordinary pendulum.

Experiment 6.—To test this, we make on a piece of paper one of the wavy curves exactly as we made the one in Fig. 6, and we tack this paper on the board L M of

the sand-pendulum, being careful that when the board is slid under the stationary pendulum the point of the funnel goes precisely over the centre line L M (Fig. 9) of the curve.

Now draw the point of the funnel aside to a distance from the line L M equal to one-half of A B, or, what is the same, from 5 to 5′ of Fig. 9. Pour sand in the funnel, and let the bob go. At the moment the point of the funnel is over L, slide the board along so that when the point of the funnel comes the third time to the line L M, it is at the end M of this line. This you may not succeed in doing at first, but after several trials you will succeed, and then you will have an answer from the pendulum as to the kind of motion it has, for you will see the sand from the swinging pendulum strewed precisely over the curve you placed under it. Thus you have conclusively proved that the apparent motion of the conical pendulum, along the line A B, is exactly like the swinging motion of an ordinary pendulum.

As it is difficult to start the board with a uniform motion at the very moment the pendulum is over the line L M, it may be as well to tack a piece of paper on the board with no curve drawn on it, and then practise till you succeed in sliding the board under the pendulum, through the distance L M, in exactly the time that it takes the pendulum to make two swings. Now, if you have been careful to have had the swing of your pendulum just equal to A B, or from 5 to 5′ on the drawing of the curve, you will have made a curve in sand which is precisely like the curve you have drawn; for, if you trace the sand-curve on the paper by carefully drawing through it the sharp point of a pencil, and then place this trace against a window-pane with the drawing of the curve, Fig. 6, directly over it, you will see that one curve lies directly over the other throughout all their lengths.

This curve, which we have made from the circle in Fig. 6, and have traced in sand by the pendulum, is called *the curve of signs*, or the *sinusoid*. It is so called because it is formed by stretching the circumference of a circle out into a line and then dividing this line, L M of Fig. 6, into any number of equal parts. From the points of these divisions 1, 2, 3, 4, 5, &c., of L M, we erect perpendiculars 2 2′, 3 3′, 4 4′, 5 5′, &c., equal to the lines *a* 2, *b* 3, *c* 4, *d* 5, &c., in the circle. These lines in the circle are called *sines*, so when we join the ends of these lines, erected to the straightened circumference by a curve, we form the curve of sines, or the sinusoid.

The sinusoid occurs often during the study of natural philosophy. We may meet with it again in our book on the nature of light, and it certainly will occur in our book on heat.

(*To be continued.*)

NOTES

UP to the present time the ignorance of those who did not know that the Archbishop of Canterbury was a degree-giving body was pardonable. It is so no longer. A serious alteration in the arrangements of these diplomas is now announced. Archbishop Tait, while he intends to dispense doctorates as before at his will and pleasure, has determined that his degree of M.A. is from December next to be a matter of examination. The standard is to be that of "honour examinations in the Universities." There is to be due choice of subjects, among which, however, Greek and Latin are not to be compulsory, though English literature is. To qualify for examination, formal testimonials required for University matriculation, with the addition of a certificate from the Bishop of the diocese whence the candidates come, are required. As the *Daily News* puts it, "the Archbishop has evidently determined to make himself into a university with all the paraphernalia which the modern conception of such a body requires." Both the London Examining Board (commonly called the London University) and Owens College are to be congratulated on the publicity now given to this singular system of granting degrees. The London Examining Body is not a teaching body, neither is the Archbishop, but the Archbishop is a university, therefore the London University system is perfect, and all methods of education whatever may be disregarded so that a standard of instruction is reached. Owens College as a teaching centre which has won its way to general esteem and confidence, may now bide its time, for this last grotesque thing calling itself a university will either make the power of granting degrees, and degrees themselves ridiculous, or direct attention to the whole subject.

ALTHOUGH the Paris meeting of the Iron and Steel Institute has not called for any lengthy notice at our hands, there are passages in Dr. Siemens' admirable address to which we cannot too strongly draw attention, and which we are anxious to place on record in our columns. He remarked that "Whilst the English, to realise a novel proposition, make bold attempts, not always carefully matured beforehand, the French systematically study a question in all its aspects, and fortify their views by careful inquiry into the experience obtained elsewhere, before they commence operations which are then carried out with all the economical and other advantages resulting from such an exhaustive preliminary inquiry. If we seek a cause for the remarkable aptitude of adapting means to special ends, to which I have referred, we shall probably find it in the advantages France and other continental countries have enjoyed for at least a generation of a more extended technical education than we could boast of, and of the personal influence which has been exercised by a line of scientific writers and experimentalists, of whom I shall only mention here such honoured names as those of Réaumur, Ebelmen, Régnault, Pouillet, Péclet, Thomas, and Le Châtelier, as belonging to the past, and of Deville, Grüner, Lan, Laurens, Jordan, Frémy, and Dumas, who are fortunately still among us. It is chiefly to such men as these that France owes her admirable system of education, which enables her to place her metallurgical establishments under the guidance of men who are scientifically qualified for the discharge of their respective duties, and for the attainment of practical results which may well excite our admiration." The organisation of the École Centrale, the creation of M. Dumas, recommends itself, as it may well do, to Dr. Siemens, and he points out that the only establishment in Great Britain comparable with the École Centrale as regards metallurgy is our School of Mines, which, "if it were installed in a capacious building, and had other branches of knowledge added to its curriculum, might easily, under the guidance of such men as Percy, Smyth, Frankland, and Huxley, be developed into an institution which would give rise to beneficial results difficult to overestimate." Had Dr. Siemens been speaking in England he would doubtless have added that this was the distinct recommendation made by the Duke of Devonshire's Commission after a long inquiry. The Government has not yet acted upon this recommendation, and the result is that students of the School of Mines have to get their mathematics when and how they can; they form no part of the curriculum. Many may think that such schools in France are too heavily weighted with mathematics, but to omit the subject altogether is to court Scylla with a vengeance. Why should not each student of the School of Mines receive, as at the École Centrale, a three years' course of general scientific education, including the higher branches of mathematics, as well as physical science, pure and applied chemistry, geology, mechanics, metallurgy, and mineralogy.

MR. H. FORBES, F.L.S., is about to leave this country to investigate the fauna and flora of Celebes, Borneo, and adjacent islands. He proposes to devote five or six years to the work.

VESUVIUS is now giving some very definite signs of an eruption.

MR. JOHN PENN, F.R.S., the eminent marine engineer, died on Monday last, at Lee, in his seventy-third year. Mr. Penn's various patents for marine engines were considered so good that no fewer than 740 British war vessels were fitted with his machinery. Among them were the *Warrior*, the *Black Prince*, the *Achilles*, the *Hercules*, and the *Sultan*. Messrs. Penn also supplied the engines for nearly all the largest war ships for the Italian, Spanish, Brazilian, German, Danish, and Peruvian Governments, and those for the yachts of the Queen, the Emperor of Russia, the Khedive, the Sultan, and the Emperor of Austria. Mr. Penn was elected a member of the Institution of Civil Engineers in 1828, and a Fellow of the Royal Society in 1859. He was also a past president of the Society of Mechanical Engineers, and had received many marks of distinction from various foreign governments.

MESSRS. BARRAUD AND JERRARD are to be congratulated on the latest issue of their fine plate containing a collection of portraits of Fellows of the Royal Society produced from photographs and printed in "permanent print." Most of the portraits and many of the *poses* are very lifelike, and the introduction of so many portraits into one picture, while retaining a certain artistic effect, has not been accomplished without a considerable overcoming of difficulties. The full-length portraits of the Astronomer-Royal, Sir J. Lubbock, Dr. Richardson, Dr. Siemens, Dr. Lister, Dr. Spottiswoode, and Prof. Martin Duncan, in the fore-front, are all excellent. A convenient key accompanies the plate.

THE Seth Thomas Clock Company have recently introduced a time-keeper with a novel and most useful addition. This consists of a perpetual calendar, the day, date, and month being shown on a second dial. We have personally tested the action of this part and can state that the mechanism takes ordinary leap years perfectly into account. Indeed, the novelty is a marvel of ingenuity. We hope later to be able to give more details.

THE Trustees of the Australian Museum seem not only to have an unhappy knack of getting into hot water, but a strong feeling that it is good to remain in it. Without entering into the quarrel between them and the late curator, any one will regret the course of action thus referred to in the last report "to his Excellency, the Governor-in-Chief":—"The Trustees regret to state that, notwithstanding their strenuous endeavours to bring all disputes with their late Curator to a satisfactory conclusion, and to relieve the institution of the custody of the whole of the property which they could admit to belong to him, that gentleman has thought fit to bring an action to recover certain medals awarded to him as Curator of the Museum in respect of property of the Museum exhibited on various occasions, at the expense of the Museum, and certain specimens and articles of clothing and furniture alleged to have been detained by the Trustees. The Crown Solicitor was authorised by the Minister of Justice and Public Instruction to defend the action, which came on for trial in the Supreme Court on November 6, and resulted in a verdict against the Trustees of 50*l*. damages for the temporary detention of the plaintiff's property, which had been returned to him before the commencement of the action, and the further sum of 850*l*. in addition to the sum of 25*l*. which the Trustees had been advised to pay into court as amply sufficient to cover the value of the articles to which the plaintiff could show even a colour of title. Notwithstanding the astonishment of the Trustees at this most unexpected result, they yielded to the advice offered by their counsel and by the court, *and offered by way of compromise to give up the medals and other property claimed, and to pay the further sum of* 175*l*. *in addition to the* 25*l*. *paid into court*, but this offer was rejected by the plaintiff, whereupon a *rule nisi* for a new trial was granted by the court."

THE daughter of Laplace has offered an excellent picture of her father to be copied. The family of Arago have likewise offered a picture of the illustrious astronomer. A large and excellent picture of Leverrier was in the hands of M. Bischofsheim, who wrote a letter to Admiral Mouchez, wishing him to take possession of it, at his earliest convenience, on behalf of the Observatory.

ON October 4–6 the annual meeting of ornithologists will take place at Berlin. The following papers will be read:—On the birds of the Danube forty years ago and at the present time, by E. von Homeyer (Stolp), president of the society; On the recent researches in the osteology and myology of birds with regard to classification, by Prof. Blasius (Brunswick); On an ornithological excursion to Hungary and Croatia, by Dr. Brehm (Berlin); On the latest collection of birds from Eastern Africa, by Prof. Cabanis (Berlin); On the birds of the Caucasus, by Dr. Radde (Tiflis); On the latest acquisitions of the Zoological Museum of Berlin, with special reference to the nests and eggs of African birds, by Dr. Reichenow (Berlin); On the importance of splanchnology with regard to systematics, by Herr Gadow (Algiers); On the progress of ornithology since 1875, by Herr Schalow (Berlin).

A LARGE and very brilliant meteor was observed at numerous places in Central Germany on September 6. Near Hanau it appeared in the south-east about 9.10 P.M., and looked like a large comet, with a solid nucleus and a long train of light stretching across the sky to the north-west. It appeared suddenly like a flash of lightning, and, when the nucleus had disappeared, the line of light yet remained, and little stars could be noticed in it by the naked eye. The total duration of the phenomenon was about thirty seconds.

ON September 15, at 6 to 7 P.M., a large meteor was observed at Montpellier. On the same day and at about the same time, one was witnessed at Tenez, and Constantine in Algeria, and a number of places at great distances from each other. It is not yet known whether it was the same body or if the earth met in its course a meteor swarm. The bolides were notable for their brilliancy and their duration. It is reported that at Constantine the phenomena were accompanied by noise.

A SHORT but violent shock of earthquake was felt at Buir, near Düren (Rhenish Prussia), on September 2, at 9.15 P.M. Indeed it is stated that since the great earthquake of August 26 shocks have been felt in that district almost daily. Another shock is reported from Remagen, on the Rhine, on September 3, at 1 A.M., and a third one from Wiesbaden and neighbourhood on September 14, at 11.35 P.M. The latter was particularly violent.

ACCORDING to the last official calculation the total receipts of the Exhibition from entrance-money will reach 13,000,000 francs up to the end of October. There are other sources of revenue and a subvention from the City of Paris. It is supposed that the deficit will not exceed 400,000*l*., which will be more than covered from various sources.

QUITE recently a most remarkable new cave has been discovered in the United States near Glasgow Junction, Kentucky. It has been investigated to a distance of no less than twenty-three miles in one direction and sixteen in another. Most of its passages are very broad, and it is stated that a carriage with a pair of horses has room to drive some eleven miles into the interior. It contains several very deep rivers, one of which has been traced to a distance of fourteen miles; further progress was then arrested, the cave narrowing too much to allow a boat to pass. The cave is described to be "most wonderful," by an American contemporary, and is said to surpass in grandeur all

other caves hitherto known, the Mammoth Cave not excepted. Some human remains, resembling Egyptian mummies, were also found in the cave. They were contained in stone sarcophagi of rough structure. The floor of the cave is extremely uneven, full of fissures and irregularities, so that it seems as if violent volcanic phenomena had taken place here. The new cave has been baptised with the more or less appropriate name Grand Crystal Cave. Our readers are doubtless aware that the Mammoth Cave is also situated in the vicinity of Glasgow Junction, Kentucky.

AMONG the resolutions passed by the International Congress on Weights, Measures, and Coins, at Paris, was the following:—The Congress learns with pleasure the progress of the metric system; it deplores that England, Russia, and the United States have not yet entered into the same path; and it is of opinion that the Governments of those countries should be solicited to give effect as early as possible to an act of progress so eminently useful to science, commerce, and international relations." The British and American members had a separate meeting, and resolved to petition their respective Governments to appoint a mixed commission to consider the adoption of the metric system by both countries, and to make all necessary recommendations for the proper legislation to secure the desired end.

THE conchological collection formed by the late Dr. Marie, of New Caledonia, has been purchased by Mr. Bryce-Wright.

AT the Royal Foundry of Munich a colossal monument cast in bronze was exhibited from September 8 to 11. It is intended for St. Louis, U.S., and represents Alexander von Humboldt; the design is by Herr von Müller, jun. The figure is some 3½ metres in height, and represents Humboldt in the freshness of manhood, leaning against a stump of a tree, upon which he has deposited his mantle; in the right hand he holds a map. The statue will be placed upon a stone pedestal, which is in course of construction at St. Louis, and which will be adorned by three relief medallions by the same artist, the one on the front showing the features of the founder of the monument, Mr. Henry Shaw, of St. Louis.

THE following are the more important addresses delivered and papers read at the sectional meetings of the German Naturalists' Association at Cassell:—Mathematical and Astronomical Section: On some new solutions of the problem of the division of the ball, by Prof. E. Hess (Marburg); On the old calculating machine of Leibnitz, by Prof. Listing (Göttingen); On the solar parallax, by the same. Prof. Listing gives the value $\pi = 8''\cdot8786$ as the most correct one at present.—Physical and Meteorological Section: On some new magnetic phenomena, by Dr. Fromme (Göttingen); On the influence of interior friction upon resonance, by Dr. Auerbach (Breslau); On a new method of employing the induction of the earth for the determination of the magnetic inclination, by Dr. Schering (Göttingen); On a new apparatus for the distillation of mercury, by Dr. Weber (Kiel); On a case of pleochroism, by Prof. Staedel (Tübingen); On a new method and apparatus to determine low tensions of vapours, by Dr. Moser (Berlin); On some applications of total reflexion, by Prof. Kohlrausch (Würzburg); On the theory of the exchange of air through porous walls, by Prof. Recknagel (Kaiserslautern); Remarks on galvanometry, by Prof. Töpler (Dresden); On the point of gravitation in curves, planes, and solid bodies, by Dr. Feussner (Marburg); Record of observations of solar spots and protuberances, by Prof. Spörer (Potsdam); On the behaviour of different heat colours in the reflection of polarised rays from metals, by Prof. Knoblauch (Halle); On the mathematical theory of friction electricity, by Dr. Schering (Göttingen); On an improvement in the hair hygrometer, by Dr. Nippoldt (Frankfort-on-the-Main). Chemical Section: On the chemical constitution of the turnip molasses, by Prof. Gunning (Amsterdam); On some new platina compounds, viz., platinofulminates, by Prof. von Meyer (Leipzig); On pyromeconic acid, by the same; On a new apparatus for the combustion of organic substances containing halogens, by Dr. Kopfer (Bonn); On the conversion of starch into sugar, by Dr. Salomon (Brunswick); On a physically isomeric modification of dinitrochlorobenzol, by Prof. Daubenheimer (Giessen); On the conditions of life of the lower organisms, by Prof. Gunning (Amsterdam); On a new method in the preparation of bromine, by Dr. Frank (Stassfurt); On some new phenomena concerning gases, by Prof. Mitscherlich. Geological and Palæontological Section: On the heat of the earth, by Herr E. Dunker (Halle); On some animal footmarks in the coloured sandstone of Carlshafen, by Dr. Hornstein; On the geological condition of the Büdingen forest, by Dr. Bücking; On an explanation of earthquakes, by Herr von Dücker; On the tridymit of Friedrichroda (Thuringia), by Dr. Luedecke; On basalt and its decay, by Dr. Franke; On the geological condition of the Kyffhäuser mountain, by Dr. Moesta. Geographical Section: On the botanical aspect of the Caucasus, by Dr. Raddé; On an exploring expedition to San José de Cucuta (South America), by Dr. K. Müller (Halle); On mountain and valley winds and their effect upon the vegetation of volcanic mountains, by Prof. Rein (Marburg); Ethnological researches in the Island of Cyprus, by Herr Schmölder (Frankfort); On the progress of the commercial relations between Europe and Western Siberia, by Dr. M. Lindemann (Bremen). Numerous papers and treatises were read at the zoological, botanical, anatomical, and physiological section-meetings, but by far the greater part were of minor interest, most of them having special reference to medicine only. The medical sections were as numerous as last year at Munich, and the attendance was, if anything, greater than on any previous occasion.

THE Aeronautical Society has issued its twelfth annual report. To it, in accordance with the expressed intention to reprint any matter of interest which might be otherwise unattainable, is annexed a reprint of a pamphlet printed in the year 1810 by Thos. Walker, of Hull, its title being "A Treatise on the Art of Flying by Mechanical Means." Mr. Walker was a portrait painter. An American would say that the treatise was a little "mixed."

THE physicists of the French Central Bureau of Meteorology are engaged in establishing a nomenclature to diminish the number of letters used in signalling.

THE American Academy of Arts and Sciences is probably one of the most active and efficient scientific societies anywhere; its *Proceedings* will bear comparison with those of any society in the old country. The part before us, including the period from November, 1877, to May, 1878, contains a number of papers of great value, the titles of which we shall give meantime, in the hope of being able to notice some of them in detail shortly. The Moon's Zodiacal Light; Undulations Observed in the Tail of Coggia's Comet, 1874; Sudden Extinction of the Light of a Solar Protuberance; On Saturn's Rings, by L. Trouvelot; Supplementary Note on the Theory of the Horizontal Photoheliograph, by Prof. William Harkness, U.S. Navy; Researches on the Substituted Benzyl Compounds, by C. Loring Jackson; Remarks on the Brain, illustrated by the Description of the Brain of a Distinguished Man, by Thomas Dwight, M.D.; Theory of Absorption-Bands in the Spectrum, and its Bearing in Photography and Chemistry, by Dr. Robert Amory; Surfaces of the Second Order, as treated by Quaternions, by Abbott Lawrence Lowell; On the Synonymy of some Species of Uredineæ, by W. G. Farlow; Metasomatic Deve-

lopment of the Copper-bearing Rocks of Lake Superior, by Raphael Pumpelly; Investigations in Quaternions, by Washington Irving Stringham; On a New Method for the Separation and Subsequent Treatment of Precipitates in Chemical Analysis, by F. A. Gooch; On Peirce's Criterion, by Benjamin Peirce; Note on the Measurement of Short Lengths, by Leonard Waldo; Contributions to the Botany of North America, by Asa Gray; Spherical Conics, by Gerrit Smith Sykes; On the Influence of Internal Friction upon the Correction of the Length of the Second's Pendulum for the Flexibility of the Support, by C. S. Peirce; Colour Perception, by G. Stanley Hall; On the Intensity of Terrestrial Magnetism at Cambridge, by Henry Goldmark. Among the foreign honorary members we find the names of J. C. Adams, Airy, Cayley, Sylvester, Clerk-Maxwell, Balfour Stewart, Stokes, Sir Wm. Thomson, Darwin, Joule, W. H. Miller, A. C. Ramsay, Sabini, Bentham, Hooker, Owen, Max Müller, Rawlinson, Gladstone, Tennyson.

THE receipts of the Giffard Captive Balloon on the first sixty days have been more than 500,000 francs. The sum spent on the construction of the balloon has been realised. It is supposed that the receipts for the month of October will be sufficient to cover the working expenses, so that M. Giffard will be rewarded for his enterprise by the possession of the balloon, machinery, and gas-producing apparatus.

A MILLION tickets have been sold at one franc each for the Paris Exhibition Lottery. Two-thirds of the sum are to be spent in purchasing prizes, the other third being destined to assist the Government in paying the travelling expenses of the working men visiting the Exhibition.

THE additions to the Zoological Society's Gardens during the past week include two Ostriches (*Struthio camelus*) from Africa, presented by the Hon. H. C. Vivian, H.B.M. Consul-General; two Secretary Vultures (*Serpentarius reptilivorus*) from South Africa, presented by C. Rivers Wilson, C.B.; an Oriental Eagle Owl (*Bubo orientalis*) from Karenee, Siam, presented by Mr. Charles Fowler; two Prairie Marmots (*Cynomys ludovicianus*) from North America, two Smaller Rattlesnakes (*Cerotalus miliarius*) from Canada, presented by Mr. Wilfred G. Marshall; two Egyptian Gazelles (*Gazella dorcas*) from Egypt, presented by Mr. Thomas Moss; three Reddish Finches (*Spermophila nigro-aurantia*), one Bluish Finch (*Spermophila cærulescens*), one Half-white Finch (*Spermophila hypoleuca*), one Tropical Seed Finch (*Oryzoborus torridus*) from South America, presented by Mr. R. C. Batterbee; three Rufous Tinamous (*Rhynchotus rufescens*) from Brazil, presented by Mr. J. A. Iliffe; two Lesser Black-backed Gulls (*Larus fuscus*), British Isles, presented by Mr. A. H. Cocks, F.Z.S.

THE FIGURE AND SIZE OF THE EARTH[1]

II.

IN addition to the measurement by Picard above-mentioned, two other arcs were measured in a north and south direction; La Hire measured northward towards Dunkirk, and Cassini southwards towards Perpignan. The result, published by Cassini in the year 1718, was as follows:—The southern arc gave 57098 toises (Picard's was 57060), and the northern 56960. This result was quite opposed to Newton's theory; it indeed favoured an elongated figure for the earth. There now began among the learned of the time a controversy which was carried on with much bitterness, between the supporters of Newton and Huyghens on the one hand, and of Cassini on the other. Cassini published the results of his measurements in his work, "De la Grandeur et de la Figure de la Terre" (Paris, 1722), and in consequence of the high reputation which he, as Director of the Observatory and member of the Academy, possessed over all France, nearly all the French *savants* took his side. But the arguments adduced by him were not such as could convince the great number of Newton's followers in all other nations. The French results were all the more objected to, that the measured arcs were much too small to allow one to base thereon a conclusion as to the form of the earth. In order to bring to an end the controversy carried on with so much violence on both sides, the French Government sent out in the year 1735 an expedition, consisting of the astronomers Bouguer, de la Condamine, and Godin, to Peru to measure the length of an equatorial degree. A second expedition, consisting of the academicians Maupertuis, Clairaut, and Lemonnier, was sent to Lapland; and while the former found the length of a degree at the equator to be 56753 toises, the latter, in connection with Celsius, found the result in latitude 66° 20′ to be 57437 toises. These results, obtained from the most careful observations and the most accurate calculations, gave the palm to the Newtonian theory, and the amount of flattening as ascertained so nearly agreed with Newton's calculation as to give the greatest confidence in his works.

It should, however, be mentioned that the Lapland measurement was much behind the Peruvian in correctness. Indeed it was soon seen that it was much more inaccurate than Picard's, and therefore the flattening of the earth was based only on Picard's and the Peruvian measurements. But the admirable execution of the Peruvian measurements was of importance also in another respect; in it, two base-measurements had been made, the southern base being considered a base of verification. This importance, which appeared at a later period, consisted in the fact that the unit of measure used in laying down the base-line, the "Toise of Peru," after it had with the greatest care been brought to Paris uninjured, was instated as the French normal measure, and this standard, at a temperature of 13° R., was appointed as the legal measure of length for France.

At a later period Freiherr von Zach reduced the length[1] of an equatorial degree to the sea-level and found it to be 56732 toises. He made use for this purpose of a second measurement at the equator, carried out by the Spaniards (assisted by Godin) between Cuenza and Mira, which embraced a length of 3° 26′ 52″ and gave 56768 toises as the length of a degree. Since the careful measurement of a degree in Peru—which put a final end to the opposition to the Newtonian theory of the figure of the earth as opposed to the view of Cassini, and proved to all the world as an undoubted fact, that the inhabitants of the earth did not live upon a perfectly spherical planet, but on one flattened at the poles; since then has also grown the universal desire for accurate knowledge of the dimensions of the earth, as from the amount of its deviation from the spherical form, we expect to form important conclusions as to the origin and development of our planet. Meantime the great progress made in methods of measurement and in instruments, combined with the beautiful results of the constantly-developing mathematical sciences, now promised the best results for new undertakings in reference to measurements of the earth.

Although the degree measurements carried out up to the middle of last century left no further doubt as to the spheroidal form of the earth, yet, as already said, the Peruvian measurement was the only one that had been carried out with the greatest possible accuracy. But on combining this arc with the French, Lapland, and other known measurements, only differing from it in point of accuracy, results differing much from each other were obtained. If we represent the polar and equatorial semi-diameters by the letters a and b, the quotient $\frac{a-b}{a}$ represents the amount of flattening. We thus obtain, by combining the Peruvian and the Lapland measurements, the value $\frac{1}{215}$, the Peruvian and French $\frac{1}{304}$, and lastly, the French and Lapland $\frac{1}{145}$. To understand in what way, by means of the data for the length of a degree, and the combining of the data for two or more different parts of the earth's surface, it would lead us to the amount of the flattening, requires considerable knowledge of the higher mathematical methods, and we must not, therefore, enter here on this part of the subject.

The great differences between the three values referred to, showed how untrustworthy were the measurements hitherto obtained, and this led to endeavours in many quarters to come nearer to the truth by better measurements. Lacaille availed himself in 1750 of his stay at the Cape of Good Hope to carry out the measurement of a degree, and found for S. lat. 33° 18′ 30″,

[1] Continued from p. 558.

[1] This probably refers to the reduction by the Baron de Zach of the observations made in the Peruvian operations.—*Mon. Corresp.*, xxvi., p. 52.

the length to be 57037 toises; and if this measurement was not carried out with the greatest care, since Lacaille could only devote two months to it, yet it was so far of no small importance, that it was the first which had been effected in the southern hemisphere. In the years 1751–53, Boscovich and Le Maire carried out a triangulation in the States of the Church, in 40° N. lat., and found the length of the degree to be 56973 toises. A degree-measurement made in the plains of Turin in 1768, between Andrate and Mondovi, gave for 44° 44′, N. lat., a degree length of 57024 toises. Mention should be made also of a series of extended measurements in Austria; and we may remark that most of the operations above referred to, as well as some of the following, were undertaken at Boscovich's instigation, while the Austrian operations were initiated and carried out by the Jesuit Liesganig. He found the length of a degree for N. lat. 48° 43′ to be 57086 toises, and for 45° 57′, 56881 toises. It may be seen from a comparison of these two values that, notwithstanding the small difference of latitude, they indicate a flattening at the poles, and if the calculation based upon these values alone give an anomalous result, it must be ascribed to the much too small difference of latitude. Indeed, errors of measurement were subsequently found in them. Finally we have to mention as belonging to this period the measurements after the old method which were carried out by direct measurement of a long meridian distance by means of a surveyor's chain. The one was in America, on the plains of Pennsylvania, by Mason and Dixon[1] over a distance of 1⅓ degree, and it gave, in N. lat 39° 11′ 56″, 56888 toises for the degree-length. The second measurement of this kind was in Bengal in 1790, by Burrow and Dalby, and it resulted in giving 56725 toises as the length of degree in N. lat. 23° 18′.

During the first forty years of the latter half of the eighteenth century a great number of geodetic operations were undertaken in various parts of the earth, and it was sought by various combinations of these measurements to ascertain the amount of polar flattening; but it was soon found that, with the exception of the Peruvian undertaking, they were too full of errors to yield a satisfactory result. The scientific men of that time soon became convinced of this drawback, and efforts were made by various academies not only to discover improved methods of measurement, but also by offering prizes to induce mechanics to perfect instruments, more especially the chronometer, so indispensable to astronomical observations. Both courses were followed with good results, and by English mechanics especially astronomical and geodetic instruments of measurement were brought to a high degree of perfection.

Strange though it may seem, France, with her revolutionary troubles coming fast upon her, was the first to commence the subsequent highly accurate geodetic operations. The multiplicity of units of measure had at this time reached its *ne plus ultra*. Not only each little territory, each separate province, but often each town had its own peculiar measure of length; and the case was nearly as bad with regard to weight, endless difficulties and disputes being the result. It was first resolved in 1790, in the French National Assembly, to come to an understanding with England on the length of the seconds pendulum, but after a year the French *savants* declared that, seeing that the seconds pendulum would be of different lengths at different parts of the earth, it would be more advantageous to adopt a given measure of the earth itself as unity, and that as such the ten-millionth part of the earth's quadrant should be taken. But, to settle this point definitely, it was necessary to measure a long arc of meridian with the greatest possible accuracy, and accordingly, March 30, 1791, it was decided to measure the meridian arc between Dunkirk and Barcelona, from which the length of the quadrant and its ten-millionth part, the metre, could be inferred. After the length of the seconds pendulum in France had been accurately observed, measuring operations were at once commenced, and thus began the great geodetic operation in France, afterwards carried on to the Balearic Isles, and in our own time but little surpassed. Notwithstanding revolutionary storms the operations were carried on and with unvarying accuracy. This measurement, effected by the method of triangulation, consisted of 120 triangles, connecting the two points Dunkirk and Montjouy, near Barcelona. The length of the arc between the two points was found to be 551584 toises.

There were also three intermediate points determined astronomically, and in order that the amount of the earth's oblateness might be inferred from this measurement alone, on Mechain's representation it was carried to the Balearic Isles, and thus the middle point of the measured arc coincided approximately with the middle point of the earth's quadrant. This extension was carried out in the years 1806-8 by Biot and Arago. The entire measured arc had now an amplitude of 12° 22′ 13·44″, the length being 705,188·8 toises, and the final result for the length of a meridian degree at 45° N. lat. was 57047 toises. It is characteristic of that time that in order to obtain the length of the metre, the conclusion of this measurement, which was undertaken for this purpose, was not waited for; but a preliminary metre measure was obtained from the results of the Peruvian, the Lapland, and the old French measurements, equal to 443·443 lines of the toise of Peru. As the results of the first-measured distance, Dunkirk to Barcelona, were known in 1797, the length was changed to 443·296 lines, and two platinum rods of that length (at a temperature of 0° C.) were prepared as standard measure, one of which was deposited in the Archives of the Republic, and the other in the Paris Observatory; two copies of these in steel served as the normal measure. On December 10, 1799, the Metre was instated as the legal measure in France, while in England the length of the seconds pendulum in the latitude of London remained as the unit of measure.[1] But the original object of the great French degree measurement, to obtain a natural measure of length, was not attained, and it is erroneous to imagine that the metre is in reality exactly the ten-millionth part of the earth's quadrant; for the length of the metre was, in subsequent degree measurements, ascertained more accurately and differently. But what was then attained was more accurate information as to the extent of the earth's oblateness.

Simultaneously with these French operations was the measurement of a degree in England, which was carried out with extreme accuracy in the year 1784, with the view of a general triangulation of the country; the measurements were made by Gen. Roy, with an accuracy not previously attained. While the angles were observed with theodolites constructed with the greatest accuracy, Roy effected the measurement of a base line with long glass tubes. Again, in the years 1800–2, was a similar geodetic operation undertaken, for the purpose of measuring a degree; the result was that for latitude 51° 20′ 54″ the length of the degree was found to be 57180 toises, and for 52° 50′ 29″·8, 57017 toises The great ellipticity of the earth resulting from these numbers gave rise to the idea that the measurements were inaccurate; but it was considered later on that mountain-masses must have exercised a disturbing influence on the plummet, and that the error must be due to this cause. In the years 1801–3 a new degree measurement under the polar circle was carried out by Svanberg and Ofverbom, the results of which, determined with great care, proved the inaccuracy of the earlier Lapland measurements by Maupertuis. For lat. 66° 20′ 12″ the length of the degree was found to be 57209 toises. The operations of Major Lambton in the East Indies, not hitherto surpassed in extent, were begun in 1802, and, as the final result, the length of the degree was found in four different places between 8° and 18° N. lat.

After so great a series of degree measurements obtained at so many different parts of the earth, it was now endeavoured, on the strictest mathematical principles, to submit them all to calculation and test their accuracy. The result was that the great French, the second north polar measurement, and the last measurement carried out in England, were shown to be of such a degree of accuracy as was needed to permit of a certain determination of the figure of the earth. All other measurements had to be cast aside as inadequate; in most of them the sources of error were pointed out, and the degree of accuracy noted, but as factors in the working-out of the final results, they could not stand. In the majority of the measurements of the latter kind the sources of error belonged mainly to two classes. The one was the rude, unsatisfactory construction of the geodetic instruments; the other concerned the astronomical part of the operation, and consisted not only in the want of accuracy in the instruments, but chiefly—and this reproach touched the greater part of the *savants* concerned—in the ignorance of the use of astronomical instruments, for of the majority it is certain that before they began their geodetic measurements, they never had an astronomical instrument in their hands.

[1] The measurement by Mason and Dixon was made with deal rods.

[1] The seconds pendulum never was the unit of length in England. But in the Act of 1824 legalising the "standard yard," reference is made to the seconds pendulum, and the length of the latter (vibrating in London) is given in inches of the standard yard, with the intention that should the standard yard be destroyed, it might through the seconds pendulum be restored.

At this period, when it was resolved to overhaul the accumulated material, subjecting to further mathematical treatment what was valuable, and leaving unregarded what was faulty, then it was resolved to work out the problem theoretically in so clear and accurate a manner as to be worthy of the high standpoint of mathematical and natural science. Thus it appeared, above all, necessary to get rid of the inequalities of the earth's surface, to reduce all measurements to an ideal form of surface, the most suitable being that (according to Gauss's definition) which the still water of the ocean would assume if it covered the whole surface of the earth. It is also defined as a surface which is at every point at right angles to the direction of a free-falling body. But in order that this ideal surface might be observed in reality, researches on a large scale would have to be undertaken on the tides, in order to obtain a mean water-level. At that time, also, theory fell upon a new and suitable method of ascertaining the amount of the earth's oblation, in the theoretical perfection of the long-known phenomena of precession and nutation. And while both the theory and the practical methods of measurement were being carried to a high degree of perfection, in spite of the political storms in nearly all European nations, new preparations were made to find a worthy solution of this problem by means of the newest and best acquisitions of science. Especially now was there a people who not only emulated the noble efforts of other nations, but whose *savants*, the first of their time, were able soon to place themselves, through their thoughtful and ingenious researches, supported by a liberal people, at the head of the efforts made by nearly all civilised nations to obtain a knowledge of the truth—this was the German.

In what follows we shall explain these acquisitions as to a knowledge of our earth which have been made in our century, and in great part by our people.

The operations which have been undertaken during the present century for the purpose of obtaining an accurate idea of the figure of the earth and its dimensions, have by no means been confined, as nearly all the early operations were, to the carrying out of degree measurements; but even in the earlier periods a method already mentioned was brought prominently forward, which would not only show the form of the surface, but from which it was also expected that conclusions could be drawn as to the internal physical condition of the crust of the earth, and the manner in which the mass under the surface is distributed—we refer to pendulum measurements. We have already seen how Richer found a difference of lengths of the pendulum in Paris and Cayenne, and after Bouguer in Peru and Lacaille at the Cape had made similar observations, an idea was obtained of the law of variation of the lengths of the pendulum at different latitudes. It was soon seen from this that the differences in length of the pendulum at the extreme points, the pole and the equator, would only be very small, and that the very nicest observations would be necessary to allow conclusions to be drawn as to the form of the earth. The Spaniards were the next who, in two ships of war, carried out measurements in very different parts of the earth, but which unfortunately proved not to be of the requisite accuracy. Shortly afterwards, a new triangulation was undertaken in France, and while Laplace sought by it as far as possible to obtain data as to the oblateness of the earth, several other *savants*, especially Biot and Arago, carried on pendulum measurements along the meridian of the great degree-measurement (Dunkirk). In connection with this new triangulation, extended and exceedingly accurate measurements of longitude were carried out. In England efforts were now made to utilise triangulation for both methods of measuring degrees, and now, especially in the southern hemisphere, pendulum observations were accomplished on a scale and with an accuracy such as had not previously been known. These observations established the fact that the southern hemisphere had no essentially different condition from the northern hemisphere. There was used for this purpose a very delicate pendulum apparatus, the "Reversible Pendulum," the inventor of which was Bohnenberger, a German. From 1822 to 1824 such observations were carried out at many coast stations as far north as the Arctic Ocean, embracing an extent of 93° of latitude.

Accurate methods of observation of this kind, as also very exact and ingeniously-constructed pendulum apparatus, were now invented and brought into use mainly by German astronomers; Bessell especially has done lasting service in this respect, his method, perfected with the greatest ingenuity, being still fruitful in results.

The principle of this method, viz., from various pendulum measurements to obtain the figure of the earth—cannot be here explained, on account of the mathematical principles involved, and we can only give some of the results obtained from the above-mentioned measurements. The first Spanish measurements gave the oblateness of the earth as $\frac{1}{300}$; the French, $\frac{1}{315}$; the English results varied between $\frac{1}{230}$ and $\frac{1}{598}$. The value obtained from the earliest mentioned astronomical observations (precesssion and nutation) was $\frac{1}{299}$. The difference of the results obtained by means of pendulum measurements could not be ascribed to erroneous observations, but rather to the unequal density of the earth, as was shown quite clearly by later measurements. It was sought, especially in Germany, to discover the amount of this disturbing influence, and to obtain observations free from these disturbances. Already, in the year 1806, a German published the thus improved results of the measurements, and obtained from the various methods of observation the following nearly accordant results:—Newton's theory gave $\frac{1}{304}$; precession and nutation, $\frac{1}{304}$; the theory of the moon's motion, $\frac{1}{304}$; pendulum measurements, $\frac{1}{321}$; and

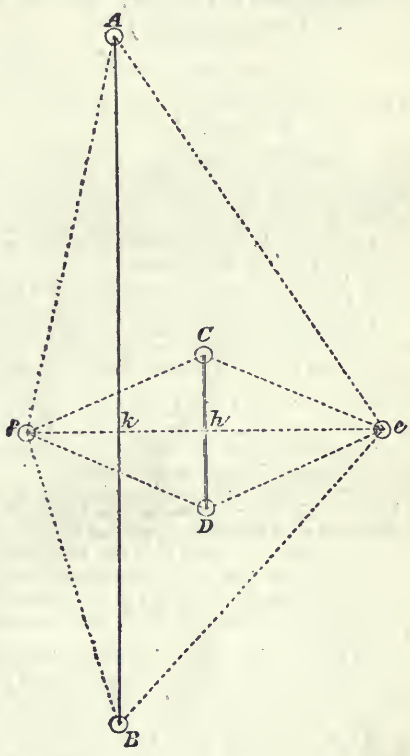

FIG. 2.

degree-measurements, $\frac{1}{304}$. Laplace and Sabine deduced, according to the newer mathematical methods, the most probable value of the oblateness of the earth, from all these results, and found, the former $\frac{1}{306}$, the latter $\frac{1}{289}$. German *savants* also repeated this calculation, and obtained, certainly not exactly the same, though very similar results; but more accurate results could only be based on more delicate measurements.

These more accurate measurements were soon carried out, mainly in Germany and Russia. Gauss, in 1821–24, measured the distance between Göttingen and Altona, and obtained for latitude, 52° 2′ 17″, 57126 toises as the length of the degree. For this purpose he had adopted greatly improved methods of observation. Schumacher made a new measurement in Denmark, and found for 54° 8′ 13″·5 the degree-length to be 57092 toises.

It may, perhaps, be interesting to show here what the improvement was which had been introduced at that time into these operations in Germany; it was the method of enlargement of the base-line, whereby the very difficult labour of base-line measurement was considerably reduced and more accurate measurements thereby became possible. For example, let the length A B be the distance to be measured, but with only a small plain surface on which a base-line can be measured (Fig. 2). The small

base-line C D is then measured with the greatest possible accuracy, and the angle formed at C and D in the directions e and f are obtained. Thus the two triangles C D e and C D f are completely given; for in each is a side (C D) and the two adjacent angles known. But thus also are their heights eh and fh given, and these added give the side ef in the great triangles. From e and f the two triangles formed towards A and B are measured, and this gives completely the two triangles A fe and B fe, as also their heights A k and B k, which added give the distance sought.[1] It will be seen at once that this method offers great advantages, especially if it be possible to obtain with the greatest accuracy the small base-line. This latter condition Bessel fulfilled at first to an astonishing degree, as he, by the introduction of a base-apparatus, attained the greatest accuracy. Bessel and Baeyer accomplished a degree-measurement between Memel and Trunz in 1831–36. They obtained for the mean latitude of the measured arc (54° 58′ 25″·5) a degree-length of 57142 toises. An operation was carried out by Maclear between 1836 and 1848 at the Cape of Good Hope, by which for south latitude 35° 43′ 20″ a degree-length of 56933 toises was obtained.

(*To be continued.*)

ON THE PRECESSION OF A VISCOUS SPHEROID[2]

I HAVE been engaged for some time past in the investigation of the precession of a viscous spheroid, with the intention of seeing whether it would throw any light on the history of the earth in the remote past. As some very curious results have appeared in the course of the work, I propose to give an account of part of them to the British Association.

The subject is, however, so complex and long, that no attempt will be made even to sketch the analytical methods employed.

In a paper of mine read before the Royal Society in May last, a theory was given of the bodily tides of viscous and imperfectly elastic spheroids; and this paper formed the foundation of the present investigation.

For convenience of diction I shall speak of the tidally disturbed body as the earth, and of the disturbing bodies as the moon and sun; moreover, in all the numerical applications, the necessary data were taken from these three bodies.

The effect of the internal friction called viscosity, is that the bodily tides in the earth lag, and are less in height, than they would be if the earth were formed of a perfect fluid.

An analytical investigation proved that the action of the sun and moon on the tides in the earth is such that the obliquity to the ecliptic, and the lengths of the day and month all become variable; the alteration in the length of the year remains, however, quite imperceptible.

But I will now explain, from general considerations, how the lagging of the tides produces the effects above referred to.

Let the figure represent the earth as seen from above the south pole, so that S is the pole, and the outer circle the equator. The rotation of the earth will then be in the direction of the curved arrow close to S. Within the larger circle is a smaller concentric one, one-half of which is drawn with a full line, and the other half with a dotted line. The full line semicircle is part of a small circle in S. latitude and the dotted one part of another small circle in the same latitude, but to the north of the equator. Generally, dotted lines indicate parts which are behind the plane of the paper.

It will make the explanation somewhat simpler, if we suppose the tides to be raised by a moon and antimoon diametrically opposite to one another; this, as is well known, is a justifiable modification of the true state of the case.

Then let M and M′ be the projections of the moon and antimoon on to the terrestrial sphere.

If the substance of the earth were a perfect fluid, or were perfectly elastic, the apices of the tidal spheroid would be at M and M′. If, however, there be internal friction, the tides will lag, and we may suppose the apices of the spheroid to be at T and T′. In order to make the subject more intelligible, the tidal protuberances are then supposed to be replaced by two equal heavy particles T and T′, which are instantaneously rigidly connected with the earth. This same idea was, I believe, made use of by Delaunay, in considering the ocean tidal friction.

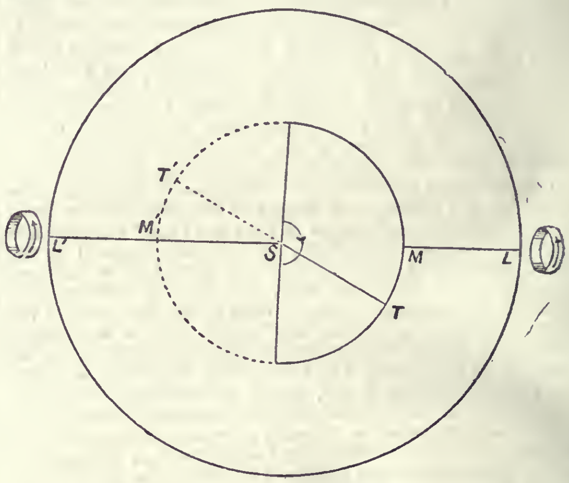
Then the attraction of the moon on T is greater than on T′; and that of the antimoon on T′ greater than on T. Hence, besides equal and opposite forces acting at the earth's centre, directly towards M and M′, there are small forces (varying as the square of the tide generating force) acting in the directions T M and T′ M′.

We will consider the effect on the obliquity first. These two forces, T M, T′ M′, clearly cause a couple about the axis L L′ in the equator, which lies in the same meridian as the moon. The couple is indicated by the curved arrows at L and L′. Now, if the effects of this couple be compounded with the existing rotation of the earth, according to the principle of the gyroscope, it is clear that the south pole S tends to approach M and the north pole to approach M′. Hence supposing the moon to move in the ecliptic, the inclination of the earth's axis to the ecliptic diminishes; in other words, the obliquity of the ecliptic increases.

Next with regard to tidal friction; the forces T M and T′M′ produce a couple about the earth's axis, S, which tends to retard the earth's rotation.

Lastly, since action and reaction are equal and opposite, and since the moon and antimoon produce the forces T M, T′ M′ on the earth, therefore the earth must cause forces on the moon and antimoon in the directions M T and M′ T′. These forces are in the same direction as the moon's orbital motion; hence the moon's linear velocity is augmented. The consequence of this is that her distance from the earth is increased, and with that increase comes an increase of periodic time round the earth.

The consequences of the lagging of the earth-tides, therefore, are an increase of the obliquity to the ecliptic, a retardation of the earth's rotation, and a retardation of the moon's mean motion.



In this general explanation it is assumed that the lagging tides are exactly the same as though the earth were perfectly fluid, and as though the tide-*raising* moon were more advanced in her orbit than the true moon, whilst the moon which attracts the tidal protuberances was the true moon. That is to say, it is assumed that the tides raised are exactly the same as though the earth were a perfect fluid, save that the time of high tide is late, and that the tides are reduced in height.

Now although this serves in a general way to explain the phenomena which result from the supposition of the earth's viscosity, yet it is by no means an accurate representation of the state of the case.

In fact the internal friction sifts out the whole tide-wave into its harmonic constituents, and allows the different constituents to be very differently affected as regards height and phase.

Thus the lagging tide-wave is not exactly such as the general explanation supposes, and the nearer does the spheroid approach to absolute rigidity the greater does the discrepancy become.

The general explanation is a very fair representation for moderate viscosities, but for large ones it is so far from correct that the tendency for the obliquity to vary may become nil, and for yet larger ones the obliquity may tend to decrease.

[1] It is here assumed that fe is at right angles to C D, and A B at right angles to fe. There is no necessity for this condition, and it could never actually occur.

[2] A paper read at the Dublin Meeting of the British Association, by G. H. Darwin, M.A., Fellow of Trinity College, Cambridge.

A complete analysis of this state of things for various obliquities and viscosities shows that there is a great variety of positions of dynamical equilibrium, some of which are stable and some unstable.

Although there is all this variety with respect to the change of the obliquity, yet the tidal friction always tends one way, namely, to stop the earth's rotation.

It has already been remarked in the general explanation that the effect on the moon is a force tangential to her orbit accelerating her linear motion, and thus indirectly retarding her angular motion. But it appears that for a very great degree of stiffness and for large inclinations of the earth's axis to the ecliptic, this force on the moon may be actually reversed; so that the retardation of the moon's motion may actually be replaced by an acceleration.

To a terrestrial observer, however, unconscious of the slackening of the earth's diurnal rotation, it would be indifferent whether the moon were undergoing true retardation or true acceleration, for in every case there would result an apparent acceleration of the moon's mean motion.

It is obvious from what has been said that we have the means of connecting the heights and lagging of the bodily tides in the earth with an apparent secular acceleration of the moon's mean motion. I have applied these ideas to the supposition that the moon has an apparent secular acceleration of 4″ per century, and I find that if the earth were a homogeneous viscous spheroid, then the moon must be undergoing a secular *retardation* of 3″·6 per century, while the earth (considered as a clock) must be losing 14 seconds in the same time. Under these circumstances the effective rigidity of the earth must be so great that the bodily diurnal and semi-diurnal tides would be quite insensible; the *bodily* fortnightly tide would, however, be so considerable that the *oceanic* fortnightly tide would be reduced to one-seventh of its theoretical amount on a rigid nucleus, and the time of high water would be accelerated by three days.

The supposition that the earth is a nearly perfectly elastic body leads to very different results, which, however, I must now pass over.

From this and various other considerations, I arrive at the conclusion that the earth has a very great effective rigidity, and that the apparent acceleration of the moon's motion affords no datum for determining the amount of tidal friction on the earth.

Sir William Thomson has made some interesting remarks about the probable age of the earth in connection with tidal friction, and he derived his estimate of the rate at which the diurnal rotation is slackening principally from the secular acceleration of the moon. He fully admitted that his data did not admit of precise results, but if I am correct in the present conclusion, it certainly appears that his argument must lose part of its force.

The investigation of the secular changes, which such a system would undergo, is surrounded by great mathematical difficulties, but I think that I have succeeded in surmounting them by methods partly analytical and partly arithmetical.

In a communication of the present kind it would be out of place to consider the methods employed, and I will therefore only speak of some of the results.

There are two standards by which we may judge of the viscosity in the present problem—first the ordinary one, in which it is asserted that it requires so many pounds of tangential stress to the square inch to shear an inch cube through so much in such and such a time; and secondly, when the viscosity is judged of by the amount by which the behaviour of the spheroid departs from that of a perfectly fluid one; a numerical value for this sort of measure is afforded by the angle by which the crest of the tidal spheroid precedes the moon, when the obliquity to the ecliptic is zero.

Now it appears that if the earth possessed a viscosity which was not at all great as estimated by the tidal standard, yet the materials of the earth, when considered in comparison with the substances which we know, would be found to be a substance of very great stiffness—stiffer than lead, and perhaps nearly as stiff as iron. I see, therefore, no adequate reason why some part of the changes, which will be considered presently, should not have taken place during geological history.

The problem was solved numerically for a degree of viscosity, which would make the changes proceed with nearly a maximum rapidity. Estimated by the tidal standard, this is neither a very great nor a very small viscosity, for the crest of the semi-diurnal tide precedes the moon by 17° 30′.

I found, then, that if the changes in the system are tracked back for fifty-six million years, we find the day reduced to six hours fifty minutes, the obliquity to the ecliptic 9° less than at present, and the moon's period round the earth reduced to one day fourteen hours.

This very short period for the moon indicates of course that her distance from the earth is small. As the moon goes on approaching the earth the problem becomes much more complex, and, for periods more remote than fifty-six million years ago, I abandoned the attempt to obtain a scale of times. The solution up to this point shows that the times requisite for these causes to produce such startling effects are well within the time which physicists have admitted to have elapsed since the earth existed.

From this point in the solution the parallel changes of the obliquity, day and month, were traced without reference to time.

It appears, then (still looking backwards in time), that the obliquity will only continue to diminish a little more beyond the point already reached; for, when the sidereal month has become equal to twice the day, there is no longer any tendency for the obliquity to diminish, and for yet smaller values of the month the tendency is to increase again.

From this we learn that, when the day is equal to or greater than half the month, the position of the earth's axis at right angles to the plane of the moon's orbit is one of dynamical stability. The whole decrease of obliquity from the present value back to the critical point, where the month is equal to twice the day, is 10°. From this point in the solution back to the initial state to which the earth and moon are tending, the obliquity to the plane of the lunar orbit was neglected. I then found that the limiting condition, beyond which it was impossible to go, was one in which the earth and moon are rotating, fixed together as a rigid body, in five hours and forty minutes. This condition was also found to be one of dynamical instability, so that, if the month had been a little shorter than the day, the moon must have fallen into the earth, but if the month had been a little longer than the day the moon must have receded from the earth, and have gone through the series of changes, which were traced backwards up to this initial condition.

This periodic time of the moon of five hours forty minutes corresponds to an interval of only 6,000 miles between the moon's centre and the earth's surface. Moreover, if the earth had been treated as heterogeneous instead of homogeneous, this interval between the primeval earth and moon would have been yet further diminished, as also would be the common periodic time.

The conclusion, therefore, appears to me almost irresistible that if the moon and earth were ever molten viscous bodies, then they once formed parts of a common mass.

With respect to the obliquity of the ecliptic, the question is one of considerable difficulty, but, on the whole, I incline to the view that, while a large part of the obliquity may be probably referred to these causes, yet that there remains an outstanding part which is not so explicable.

Besides the results, of which the outlines have been given, I have obtained some others which, as I believe, will aid in the formation of a modified edition of the nebular hypothesis—such as some of the changes to which an annular satellite would be subjected.

One of the collateral results, which appeared in considering the secular changes of such a system as the earth, moon, and sun, was that a large amount of heat would have been generated in the interior of the earth by means of friction. If, then, it is permissible to suppose that any considerable part of these changes had taken place during geological history, Sir William Thomson's problem of the secular cooling of the earth would require some modification.

The magnitude of the undertaking has not allowed me time as yet to apply these ideas to the questions of the eccentricity and inclination of the orbit of the satellite, nor to the cases of other planets besides the earth.

I think, however, that I see in Asaph Hall's wonderful discovery of the Martian satellites, a confirmation of this theory. Their extreme minuteness has, I think, preserved them as a standing memorial of the primitive period of rotation of that planet. The Uranian system, on the other hand, appears, at least at first sight, a stumbling-block.

It is easy to discern in the planetary system many *veræ causæ* which tend to change its configuration, but it is in general very hard to give any quantitative estimate of their effects.

It will have been seen that in the investigation of which I have given an imperfect account, free scope has been given to speculation, but that speculation has been governed and directed in every case by appeal to the numerical results of a dynamical problem, and I therefore submit that it stands on a different footing from the numerous general speculations to which the nebular hypothesis has given rise.

NATURAL SCIENCE IN HUNGARY IN THE LAST TEN YEARS

FEW of the readers of NATURE are aware that Hungary has of late years become the scene of active efforts in science, and especially the natural sciences.

The following sketch of an article, written by Mr. Coloman Szily, member of the Academy of Sciences, and Professor of Physics at the Polytechnic of Budapest, and published in the *Budapesti Szemli* (*Budapest Review*), may therefore not be altogether without interest.

The first active sign of native scientific life in this direction in Hungary was the founding of the Academy of Sciences in 1830. Up to that time there were single men of science, but no organised scientific life. But the chief object aimed at by the Academy was the cultivation of the national language, and the excessive zeal with which it pursued this aim did much harm to the cause of the natural sciences here. An erroneous attempt to substitute purely Hungarian words for the mathematical and other scientific expressions universally accepted elsewhere, threw great obstacles in the way of the progress of the natural sciences in our country.

This and other errors soon brought a reaction.

The "General Assembly of Physicians and Naturalists" was soon started amid general enthusiasm. The meetings of the assembly were held yearly in different cities from 1841 up to 1848, and then renewed in 1863, after a cessation of fifteen years, caused by political events. A yearly report was issued, containing the various papers read at the meeting, as well as an account of physical characteristics of the district in which it was held.

Far more brilliant was the success reached in the cultivation and promulgation of the natural sciences by the "Természettudományi Társulat" (Society of Natural Sciences), which was started at the same time. By 1848 the number of the members rose to more than 400. Its first yearly report was then issued, and a contract made for the starting of a scientific magazine, entitled "Magyar Iris." This powerful start, which was made independently of the Academy, and which proved of ever-increasing importance, could not remain without effect. In 1844 a proposition that the two classes of mathematicians and naturalists might hold their meetings and carry on their financial and other operations separately from the rest was partially accepted. Some years later (1861) it only required a single lecture (of Prof. Joseph Izabo's) to bring the whole Academy to pronounce a resolution against the attempt to Magyarise the nomenclature.

In the meantime the events of 1848-49 were followed by a long period of despotism, which tended to paralyze all attempts at association. The most distinguished men of science were forced off the field of action, the Academy could hold no meetings, the Society of Natural Sciences was on the brink of dissolution, its members were scattered, its collections had to be given away for lack of funds to pay the rent of the accommodation needed for them, and it was barely able within ten years to publish two of its yearly reports.

Between 1850 and 1860 the nation began to breathe more freely. Its very first efforts were turned towards the advancement of science. A very fine building was raised for the Academy, and its capital considerably increased, by means of private subscriptions. It thus became able to do much more than it did previously, both for the improvement of our native language and for the cultivation of the various branches of science. In 1860 it appointed a committee of mathematicians and naturalists, whose duty it was to explore the whole country and give an account of its natural and technical features. Ever since the year 1868 Government has devoted the yearly sum of 5,000 florins to the furtherance of the labours of this committee. But this sum frequently proves insignificant. Fourteen volumes of the publications of the committee, entitled, "Scientific Treatises Relating to Home Topics" (Termiszettudományi közleménysk, vonatkozólag a hazai viszonyokra), edited by its secretary, Prof. Joseph Szabo, have already appeared. At the same time with this the Academy started a second series of periodicals for publishing mathematical and scientific treatises, not confined to topics within the limits of our country. They appeared yearly from 1860 to 1867, six volumes in all.

After the renewal of constitutional life in 1867 our naturalists were also filled with a strikingly-increased zeal for labour. The Academy has up to the present day issued thirty-two volumes in all. Many articles, treating of the original researches of our naturalists, have appeared in foreign periodicals. The meetings of the department of natural sciences in the Academy have of late borne witness to a truly diligent and scientific spirit, there scarcely being one in which less than six or eight treatises have been presented upon topics of original research.

In 1868, though no preliminary agreement had taken place between the two institutions, the department of Naturalists of the Academy, having arrived at the conviction that the popularising of the natural sciences was not their calling, abandoned the attempt, and decided that they should henceforth direct their efforts solely to the cultivation of the sciences and the making of scientific researches in our country, while the Society of Natural Sciences took upon itself the spreading and popularising of them. To this end the Society started a monthly periodical; the number of members of the Society rising in the very first year of its existence from 600 to 1,600, the second year to 2,200, until at present it borders upon 4,800. A short time later the Society began to arrange lectures connected with experiments for the benefit of the public. These lectures have now been kept up for eight years, and the large lecture-hall in which they have been held has always been crowded with hearers. As long as it was possible these lectures were published in the *Journal of Natural Sciences*; now, however, they appear in the form of a new series of publications under the title, "Collection of Popular Treatises upon Topics pertaining to the Natural Sciences." In 1872 the Society again started a new undertaking, namely, the translating into Hungarian and issuing of foreign works of a popular kind upon the natural sciences. The result of this undertaking, which has enjoyed the support of 1,500 subscribers, as well as a yearly aid from the Academy, has up to the present time been the issuing of twelve volumes, such as "Geologie der Gegenwart," by von Cotta; Darwin's "Origin of Species," Helmholtz's "Populäre Vorlesungen," Huxley's "Lessons in Physiology," Lubbock's "Prehistoric Times," Proctor's "Other Worlds than Ours," and Tyndall's "Heat as Motion." An Anthology has also been compiled, containing a treatise from every scientific author who has contributed to the popularising of the natural sciences, from the time of Arago and Humboldt downwards, and a volume containing the complete works of the late Julius Greguss. These books always find a large number of purchasers.

But there is another branch of activity which is of more importance, perhaps, than all those, namely, its efforts for the encouragement of original research. From 1870 the legislature of our country, in appreciation of the labours of the Society, has voted a yearly sum at first of 5,000, and afterwards of 4,000 florins, for the promotion of such researches as stand most nearly connected with the interest of our country, and the publication of an account of the same. In this series of publications the following have appeared up to the present time:—"The Rise and Fall of Tide in Fiume Bay," by Emile Stahlberger; "The Ice Grotto of Dobsina," by Dr. Joseph Alexander Krenner; "Sketch of the Ligaridas of Hungary," by Dr. Géza Horváth; "The Spiders of Hungary: Vol. I. General Part," by Otto Hermann; "The Iron Ores and Iron Products of Hungary, with Special Reference to the Principal Chemical and Physical Qualities of the Iron," by Anton Kerpsly.

In searching out and making known the physical characteristics of our country, the Society of Geologists (Magyar földtani társulat), founded in 1851, can also boast considerable merits. The Society also publishes a monthly periodical under the title of *Geological Review*.

In 1872 there was also a Geographical Society founded, which did not aim so much at the advancement of geographical researches as at keeping the public informed of any progress made on this field by means of a two-monthly review.

This active interest in the natural sciences is not confined only to our capital, but has taken root throughout the country. To prove this we have but to note the interest manifested in the labours of the Society of Natural Sciences in all grades of

society everywhere, and the fact that societies under various titles, but all aiming at the cultivation of the natural sciences, were formed in many of our larger towns as early as between 1850–60, and more still of late years.

There is another circumstance worthy of notice, which affords perhaps a clearer illustration of the general interest in the natural sciences, and diligence on the field of the same, than even the rise and progress of the various societies already mentioned. It is the constant increase in the number of scientific periodicals, of which the following are already in circulation, besides the publications of the academy and the three societies of which we have spoken :—

(1) *Nature* (*Természet*), which appears every two weeks, and is now in the tenth year of its existence; (2) *Polytechnical Journal* (*Müessetemi lapok*), a monthly periodical for mathematical and technical treatises; (3) *Reports of the Meetings of the Society of Physicians and Naturalists in Klausenburg*, started in 1876; (4) *Botanical Papers*, a monthly, started in 1877; (5) *Leaves of Natural History*, a quarterly periodical, started in 1877, and edited by the Hungary National Museum. At the end of each volume is a review of the contents, written either in French or German, in order to be understood in foreign countries, and containing either a complete translation or an abstract of all the more important articles in the volume; (6) *Magazine of Natural Sciences*, a two-monthly periodical, started in 1877, and edited in Temesvár by the Association of Naturalists of South Hungary.

To recapitulate briefly what has been said, there are in Budapest, besides the department of natural sciences in the Academy, three societies, the object of which is exclusively the cultivation of the natural sciences, and one of which is of dimensions that, considering the total number of inhabitants, are scarcely equalled anywhere in Europe. In other parts of our country we have in all six societies of naturalists, and there are in circulation nine scientific periodicals, not one of which enjoys any aid from the State, all being supported exclusively by the readers.

These societies, however, are not the sources of science, but merely, so to speak, its conducting pipes. The sources of it spring from the collections and laboratories of the universities. The progress made here of late years has also been considerable. Our university, which was greatly neglected up to the year 1850, has of late taken such a start forward that its condition of ten years ago is not to be compared to its present state. The number of professors' chairs pertaining to the natural sciences (including those of the University and the Polytechnic of Budapest, and the University of Klausenburg) now amounts to three times what it was previously. The greater part of these chairs are occupied by young professors, who have been educated at foreign universities, under the instruction of the most distinguished men of science. Each one has a respectable sum of money at his disposal for cabinet and laboratory purposes. Separate buildings have been raised and equipped as institutes of natural sciences, such as the Chemical and Physiological Institute, connected with the University, which stands under the direction of Prof. Charles Than, and already enjoys a wide-spread renown in Europe. The buildings intended for a clinic are nearly completed, and soon the Institute for Physics, the Mineralogical and Zoological Institute, and the buildings of the Polytechnic will be raised in their turn. The number of the students of philosophy increases with striking rapidity, and some of the most distinguished of these are yearly sent out to foreign universities at state expense, with a view to their afterwards accepting appointments in their own country.

All these things clearly show that Hungary has within the last ten years made striking progress in the field of natural sciences, so that the distance which separated her in this respect from her western neighbours, has grown palpably less. Would that providence should permit her to continue the work thus begun! J. M. A.

PUBLISHERS' ANNOUNCEMENTS

MESSRS. WILLIAM BLACKWOOD AND SONS announce "The Transvaal of To-day: War, Witchchraft, Sport, and Spoils in South Africa," by Capt. Alfred Aylward, late Commandant, Transvaal Republic. Capt. Aylward commanded the Leydenberg volunteers on the Boers' frontier until the Republic was annexed by the British, and from the prominent part he played in Transvaal politics, as well as from his knowledge of the country and his experience of Kaffir warfare, his book may be expected to throw some light upon questions that are now attracting public attention.

MESSRS. KEGAN PAUL AND CO. announce that they will add to their International Scientific Series in October, a "History of the Growth of the Steam Engine," by R. H Thurston, Professor of Mechanical Engineering in the Stevens Institute of Technology, Brooklyn. The volume will give a history of the discoveries, inventions, and many ingenious experiments that gradually led to the success of the steam engine in the last century, and will be illustrated with fifteen portraits and 148 engravings on wood. This work will be followed speedily by Prof. Huxley's volume on "The Crayfish: an Introduction to the Study of Zoology." Prof. Alexander. Bain's "Education as a Science;" and Dr. H. Charlton Bastian's treatise on "The Brain as an Organ of Mind." Two translations from the French will also be included in the series before Christmas, namely, "The Human Race," by Prof. A. de Quatrefages, and "The Brain and its Functions," by Dr. J. Luys. The same publishers announce "The Geology of Ireland," by G. Henry Kinahan, M.R.I.A., &c., of Her Majesty's Geological Survey; with numerous illustrations and a geological map of Ireland; to be ready in October. "Etna; a History of the Mountain and its Eruptions," with maps and illustrations, by G. F. Rodwell, F.R.A.S., F.C.S. "Flowers and their Unbidden Guests," by Dr. A. Kerner, Professor of Botany in the University of Innsbruck; translation edited by W. Ogle, M.A., M.B.; with illustrations. "Mind in the Lower Animals in Health and Disease," by W. Lunder Lindsay, M.D., F.R.S.E., F.L.S., Hon. Member of the New Zealand Institute; Vol. I. Mind in Health; Vol. II. Mind in Disease. "History of the Evolution of Man," by Prof. Ernst Haeckel, Author of "The History of Creation;" two vols., with numerous illustrations. "Gaur: its Ruins and Inscriptions," by the Late John Henry Ravenshaw, B.C.S.; edited by his Widow; with forty photographic illustrations, and fourteen facsimiles of inscriptions. These three last books will be ready for publication in November.

MESSRS. REEVE AND CO. have just published the fourth edition of Bentham's "Handbook of the British Flora." The principal alteration in this edition has been the giving the first place to the Latin names of the genera and species. The attempt made in previous editions to establish an English scientific nomenclature, in imitation of the French and German ones introduced into several standard Continental floras, has, we regret to say, proved a failure.

MESSRS. MACMILLAN AND CO. will publish, in the course of the season, the following new books and new editions:—"Sport and Work on the Nepaul Frontier, or Twelve Years' Sporting Reminiscences of an Indigo Planter," by "Maori," with Map and Illustrations; "Coal, its History and its Uses," by Profs. Green, Miall, Thorpe, Rücker, and Marshall, of the Yorkshire College, Leeds, with numerous Illustrations, 8vo; "Chemistry: a Treatise on," by Profs. Roscoe and Schorlemmer, of the Owens College, Manchester, vol. ii., "Metals," part 1, 8vo; "Gegenbaur's Comparative Anatomy," a Translation revised with Preface by Prof. E. Ray Lankester, F.R.S., with numerous Illustrations, medium 8vo; "A System of Medicine," Edited by J. Russell Reynolds, M.D., F.R.S., vol. v., completing the work; "Modern Realism Examined," by the late Prof. Herbert, Edited by Prof. James M. Hodgson; "Science Lectures at South Kensington," vol. ii., crown 8vo; "The Theory of Sound," by Lord Rayleigh, M.A., F.R.S., vol. iii., 8vo; "Heat," an Elementary Treatise, by P. G. Tait, Professor of Natural Philosophy at Edinburgh, with numerous illustrations, crown 8vo; "Sound" (NATURE series): a series of simple, entertaining, and inexpensive experiments in the phenomena of sound, for the use of students of every age, by Alfred Marshall Mayer, Professor of Physics in the Stevens Institute of Technology, &c., &c.; "Ismailïa" by Sir Samuel W. Baker, Pasha, a narrative of the expedition to Central Africa for the suppression of the slave trade, organised by Ismail, Khedive of Egypt, with maps, portraits, and numerous illustrations by Zwecker and Durand, new and cheaper edition, one vol., crown 8vo; "A Ramble Round the World," by M. le Baron de Hübner, formerly Ambassador and Minister, translated by Lady Herbert, new and cheaper edition with numerous illustrations, crown 8vo.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE

It has been determined to give a course of lectures on Agricultural Chemistry at the High School, Kelso, and the first of the series, at which Sir Geo. Douglas presided, was delivered on the 19th inst. by Mr. Wm. Ackroyd, from the Science Schools, South Kensington.

Prof. Marignac, after having filled for a period of thirty-eight years the Chair of Chemistry at the University of Geneva, with the greatest distinction, has recently resigned. He has been replaced in the chair by Prof. Graebe, from the University of Königsberg.

SCIENTIFIC SERIALS

Bulletin de l'Académie Royale de Belgique, No. 6, 1878.—In this number M. Spring communicates some interesting preliminary results obtained from enormous pressure exerted on the fine powder of some solid bodies (nitrates of sodium and potassium, sawdust, chalk, &c.). Homogeneous blocks were thus produced, harder and more resistant than if they had been obtained by fusion. Two of them were found translucid, and did not present the least vestige of the particles which were united to form them. A force of 40,000 atmospheres was employed, but of this—the friction of the apparatus being enormous—only about half was disposable pressure.—Some experiments with regard to the action of atropine and physostigmine on the heart of the frog, and in connection with the physiology of the vagus nerve, are described by MM. Putzeys and Swaen.—From a careful examination of some Chilopodan Myriapoda, especially several large Scolopendra from Java, M. Jules M'Leod has succeeded in detecting the true venomous glands in the substance of the forcipular foot-jaws. The structure of these organs is detailed.—M. De Heen has sought to determine the viscosity of liquids from the retardation of a small spheroidal glass runner allowed to descend in a tube of 3 m. height, filled with different liquids. He deduces numerical values, which he considers to represent the *coefficients of fluidity* of the liquid. Objection is taken, however, to his formula by MM. Valerius and Montigny, who report on the paper.

The *Zeitschrift der oesterreichischen Gesellschaft für Meteorologie* (vol. xiii., Nos. 19 and 20) contains the following more important papers:—On the conditions of temperature in the United States, by Dr. A. Woeikoff.—Appeal to meteorologists to make observations of clouds, by Dr. H. Hildebrandsson.—On a new balance thermograph, by Dr. A. Sprung.—On the estimation of ozone, by Albert Lewy.—On the origin of atmospheric ozone, by Dr. Leuder.—On the climate of Queensland, by Herr Hann.—On the local winds of the Hiberian peninsula, by Herr Hellmann.

Kosmos, August.—The inhabitants of the planets, by C. du Prel.—Harvey on generation: a study, by W. Preyer.—Insects as unconscious florists, part 2, by Hermann Müller; with wood-cuts illustrating potentilla, ranunculus, lychnis, daphne, crocus, &c.—On the struggle of languages in the Valais, by Alexander Maurer.

Zeitschrift für wissenschaftliche Zoologie, vol. xxxi. part 1.—On the Siphonophora (Hydrozoa) of deep water, with descriptions of new species of Rhizophyda and Bathyphysa, by Th. Studer; three plates.—Contribution to the morphology of Oxytrichidæ, by V. Sterki; one plate.—On *Trichaster elegans*, by H. Ludwig.—On Loxosema, by O. Schmidt.—On the Tomopteridæ, by F. Vejdovsky; two plates.—Contribution on the Caprellæ, by A. Gamroth; three plates.

Morphologisches Jahrbuch, vol. iv. part 2.—Contributions on the formation, fertilisation, and segmentation of the animal ovum, by Oscar Hertwig, part 3, continuing and confirming his previous researches; three plates, with figures of ova of Nausithoë, Physophora, Helix, Unio, Tellina, Sagitta, and many others.—On fossil vertebræ: the Cestracionts, by C. Hasse; fifty-five pages, three plates; one containing coloured diagrams of vertebræ to illustrate a scheme of the evolution of fishes.—On *Gorgonia verrucosa*, by G. von Koch.—On the retrogression of eyes in Arachnida, by A. Stecker; one plate, illustrating Chernes and Chelifer.—On the osteology of the gorilla, by C. Aeby; with five wood-cuts.

SOCIETIES AND ACADEMIES

London

Entomological Society, September 4.—Fred. Smith, vice-president, in the chair.—Mr. David Price of Horsham, Sussex, was elected as a Member, and Capt. Thos. Broun, of Auckland, New Zealand, as a Subscriber.—Mr. Rutherford exhibited two specimens of an orthopterous insect *Palophus centaurus*, West, from Old Calabar.—Mr. F. Smith exhibited a specimen of the fruit of the so-called "locust-tree" (*Hymenea conbaril*), from British Guiana, forwarded to Dr. Sharp from Mr. Harper. The fruit on being opened had been found to contain three living specimens of a weevil (*Cryptorhynchus stigma*, Linn.), a cocoon containing the chrysalis of a moth, together with the remains of one or more such cocoons, and lastly, a small parasitic hymenopteron (an Ichneumon allied to *Chelonus*). Mr. Smith also exhibited a specimen of *Melolontha vulgaris*, which had lately been found alive under turf at the bottom of a box in which the larva had been placed last April, thus making it appear probable that the insect assumes its perfect state underground a long time before making its actual appearance.—Mr. Champion exhibited a series of *Spercheus emarginatus*, taken at West Ham, Essex.—Mr. Jno. Spiller exhibited some so-called "jumping-seeds," received from Mexico, and contributed remarks thereon.—The secretary exhibited a photograph of a fossil butterfly, *Prodryas persephone*, Scudd., received from Mr. Scudder. The insect represented was in an excellent state of preservation, and had been found in the tertiary formation of Colorado.—Mr. Smith stated that having recently had occasion to refer to the Linnean collection in the apartments of the Linnean Society, he regretted to find it had been allowed to fall into a state of complete neglect.—Mr. Swinton communicated a paper on the vocal and instrumental music of insects.—Mr. Waterhouse read a paper entitled notice of a small collection of coleoptera from Jamaica, with descriptions of new species from the West Indies.

Philadelphia

Academy of Natural Sciences, April 30.—On the bridging convolutions in primates, by A. J. Parker.

May 14.—Elements of the sidereal system, by Jacob Ennis.—Descriptions of new species of North American bees, by E. T. Cresson.

May 28.—Transition forms in crinoids, and description of five new species, by C. Wachsmuth and F. Springer.

June 4.—The law governing sex, by T. Meehan.

July 9.—On pelagic amphipods, by T. H. Streets.

DOBSON'S CATALOGUE OF BATS

Catalogue of the Chiroptera in the Collection of the British Museum. By George Edward Dobson, M.A., M.B. London. (Printed by Order of the Trustees. 1 vol., 8vo. 1878.)

THOUGH Mr. Dobson's work is modestly termed a "Catalogue," it amounts, in fact, to a complete monographic essay on what has hitherto been justly regarded as the most difficult and the least understood, as it is the most numerous, of all the orders of mammals. Not only are the families and genera of the Chiroptera well characterised in this volume, and all the known species described in concise though sufficiently explicit terms, but synopses of the members of each genus are added in order to facilitate their determination, and excellent notes on the comparative anatomy, habits, distribution, and position of these animals are given, whenever such information is available. Mr. Dobson, it is true, has had unusual opportunities in dealing with this subject, but it is not the less to his credit that he has taken such good advantage of them. Having commenced his studies upon the bats during his official residence in India, he has been able to make himself personally acquainted with the forms inhabiting that country, and likewise to examine the types of Blyth's descriptions in the Indian Museum at Calcutta, without sight of which it would have been impossible to recognise what was intended by them. In this country the late Dr. Gray turned his attention at various times to the Chiroptera, and besides describing numerous species even more hastily and imperfectly than Mr. Blyth, indulged himself in the evil practice of altering some of the types upon which he had found his genera and species. Having the national collection at his command, Mr. Dobson has been able to reduce all these eccentricities into order. On the continent the accomplished zoologist of Berlin, Dr. W. Peters, is almost the only naturalist who has of late years worked at this perplexing group of mammals. Dr. Peters has published many excellent memoirs on various genera of bats in the *Monatsberichte* and *Denkschriften* of the Berlin Academy, in the course of which he has given us an account of his examination of numerous obscure types of the older author. Mr. Dobson has worked up the results of these memoirs into his monograph, and has at the same time had the advantage of examining in the Museum of Berlin the materials upon which Dr. Peters has based many of his conclusions. Mr. Dobson has also visited the great museums of Leyden and Paris, and has studied the specimens described by Temminck, Geoffroy St. Hilaire, and A. Milne-Edwards, belonging to these collections. In fact he has had under his eyes nearly all the available materials for a study of the group, unless it be the specimens collected by Natterer in the Imperial Zoological Cabinet at Vienna, and a few types lately described by Mr. Allen in America. Under these circumstances Mr. Dobson's so-called "Catalogue" has, as we have already remarked, become a monograph of a very high order of merit, and one which reflects the greatest credit upon the talents and the industry of the author.

Mr. Dobson recognises 400 species of the order Chiroptera, which he divides primarily into "Mega-chiroptera" and "Micro-chiroptera." We do not quite see the advantage of these newly-coined names over the more usually employed terms of "Frugivora" and "Insectivora," even if they had been classically compounded, which, unfortunately, is not quite the case. Certain it is that the new terms are not more absolutely true than the older ones, as some of the smaller "Mega-chiroptera" are inferior in size to the larger "Micro-chiroptera." About seventy species of the Frugivorous bats are allowed full rank in the present work, the author, who holds very sound views on the true limits of species, having reduced to the grade of sub-species some of the forms recognised by previous writers. The more numerous "Micro-chiroptera" constitute five families, namely the Rhinolophidæ, Nycteridæ, Vespertilionidæ, Emballonuridæ, and Phyllostomidæ, according to Mr. Dobson. This arrangement is not very different from that of Dr. Peters in 1865. Dr. Peters' "Megadermata" do not quite correspond to Mr. Dobson's "Nycteridæ," and Mr. Dobson puts the "Brachyura" and "Molossi" of Dr. Peters together in his family "Emballonuridæ." There are other minor differences, but it is satisfactory to see that these two great authorities on an obscure group of mammals are so nearly agreed as to their general arrangement.

Mr. Dobson has not made any suggestion as to the special use of the extraordinary adhesive discs which are attached to the inferior surface of the thumbs of *Thyroptera tricolor*, except by designating them as "highly specialised climbing organs." This they certainly are, but to climb what are they highly specialised? We have been told by one who has observed them in their native haunts that these abnormal bats are always found adhering to the smooth stems of certain palm-trees on the upper Amazons, and it is for this purpose, no doubt, that these peculiar suckers are provided. As regards the vexed question of the true blood-sucking bats, Mr. Dobson seems to adhere to the now generally-received opinion that the only certainly-known sanguivorous species are the two Desmodontes (*Desmodus rufus* and *Diphylla ecaudata*), in which the alimentary canal is specially modified in relation to their peculiar diet. *Vampyrus spectrum*, formerly considered so formidable a blood-sucker, is probably purely frugivorous, and older writers have made similar accusations against certain species of *Glossophaga* and *Artibeus*. But *Desmodus* is the only culprit that has been actually "caught in the act," and naturalists are always somewhat incredulous in cases of merely circumstantial evidence. As regards the peculiar structure of the stomach of the Desmodontes it is not quite true, as stated by Mr. Dobson, that no other zoologists but Prof. Huxley and Dr. Peters "seem to have been aware of this remarkable departure from the simple type of that organ found in all other Micro-chiroptera." As Herr v. Petzeln. has lately told us,[1] this peculiarity did not escape the vigilant eyes of the late Johann Natterer, who recorded it in his note-book in 1824, although his remarks were never published, and, if we are not mistaken, Prof. Reinhardt has also noticed it.

Mr. Dobson's letter-press is illustrated by thirty litho-

[1] Sitz. k.k. zoolog.-botan. Ges. in Wien, vol. xxviii.

graphic plates drawn under his superintendence by R. Mintern. Although not so finished in execution as those of the late Mr. Ford, or quite so clear in detail as what Franz Wagner has done for Dr. Peters in the same style, these plates form a great addition to the volume, and exhibit some of the special structures of the group in a very efficient way.

Of the general merits of the Zoological Catalogues of the British Museum, and of the credit due to the staff of the Zoological Department for their preparation in the face of many difficulties, we have spoken in a previous notice of one of this same series.[1] It is much to be regretted, however, that more pains are not taken to make the existence of these most valuable publications known to the world. No publisher's name being on the title-page, it is difficult for the general public to know how to procure them, and no information on the subject is given in the volumes themselves. So far as we know, they are not advertised in any way, and no copies are sent out for review—certainly not to the office of NATURE;[2] so that it is only by chance that one becomes aware of their issue. On the Continent there are many complaints about the difficulty of procuring copies, and naturalists in London receive frequent applications from their brethren abroad on this subject. This might be all remedied by putting a publisher's name on the title-page—a course adopted by all our principal scientific societies for their publications—or even by adding to each volume a list of the series, with some directions as to how and where they are to be obtained. Another mystery connected with these catalogues which we have never been able to understand is why the authors of them should not be allowed to write their own prefaces. In some of the older volumes even the author's name is not given on the title-page. This privilege has been conceded of late years, but the prefaces continue to be written by the "keeper of the department." We are told this is a "regulation of the trustees"—an answer given, we may observe, about many other rules and regulations at the British Museum, of which no one can understand the utility.

TIDY'S "HANDBOOK OF CHEMISTRY"

Handbook of Modern Chemistry, Inorganic and Organic, for the Use of Students. By Charles Meymott Tidy, M.B., F.C.S. (London: J. and A. Churchill.)

THIS work is divided, as is usually the case with chemical text-books, into three large divisions; the first containing the chemistry of non-metallic bodies, the second the chemistry of the metals, and the third the chemistry of organic substances.

In the first two chapters, preliminary to those discussing systematically the natural occurrence, preparation, and properties of the non-metals, the author describes the more general principles involved in the science, embracing such topics as nomenclature, atomic and molecular combination, combination by volume, atomicity and quantivalence, &c. The subjects here touched upon are clearly dealt with, and Mr. Tidy's style of writing cannot fail to attract the attention of the reader.

The subsequent portion of the book, consisting of Chapters III. to IX., embraces the consideration of the individual properties of the different non-metallic elements; and although this part of the work abounds in valuable and, as far as we can see, accurate information, there is an important point with regard to it upon which we cannot thoroughly congratulate the author; namely, the order in which he has arranged the non-metallic elements. He commences with oxygen and finishes with hydrogen. We cannot at this moment see, nor can we find any explanation in the preface or otherwise, stating why this particular order should be adopted; and we are inclined to think that, for the sake of instruction in chemical order and classification, it indicates a defective appreciation of the wants of the student. It appears to us that, keeping this point in view, the order of such a text-book as Mr. Tidy's should be that in which the elements forming the least complex compounds are first taken, then those which possess a larger number of compounds and of a more complicated nature.

This becomes evident if it be considered what the student is met by in reading this portion of the book, where, instead of first being made acquainted with the properties of hydrogen, the body now almost universally adopted as our standard of reference for the atomic weights of the elements, for the densities of gases, &c., he has to consider oxygen "a common and important substance, certainly," but not one which is now taken as our standard, or which forms the simplest combinations, so far as its own relations are concerned, with other bodies. The reader then passes, in the next chapter, to the consideration of the group of elements, consisting of fluorine, chlorine, bromine, and iodine; bodies having a simpler volume relation to hydrogen than oxygen has: and he is then introduced to a long series of compounds, the oxyacids of the halogen series, where three elements take part in the combination before he has become acquainted with compounds containing only two, such as hydrochloric acid or water. Nay, more, he has to consider acid bodies containing hydrogen—reads equation after equation in which the body water occurs as a product of decompositions, without his previously having learned anything either about the preparation and properties of hydrogen, or the composition of water.

Again, in the arrangement of the subjects treated of in the chapter dealing with the special consideration of hydrogen (Chap. IX.) we think there is room for improvement; and that it would be better to adopt an arrangement depending on the simplest volume relations of the substances, placing them in the series monatomic, diatomic, triatomic, and so on, instead of first taking water where the ratio of hydrogen to the other substance is 2 : 1, then the halogen compounds of hydrogen where the ratio is more simple, viz., 1 : 1, then its compounds with nitrogen, phosphorus, and arsenic, where the ratio is 3 : 1, then back again to sulphuretted hydrogen, where the ratio is 2 : 1, and finally, to the simple compound of carbon and hydrogen with the ratio 4 to 1. If the student is at all thoughtful, and has paid any attention to the sections on "combination by volume," &c., which we have already stated to be clearly written, he will find himself at the end of the consideration of the non-metals rather at a loss to form any idea of order or classification as regards chemical bodies.

[1] See our review of Sharpe's "Catalogue of Birds," NATURE, vol. xvi. p. 541.

[2] Since the above was in type a copy of Dobson's "Catalogue" has been sent us by the author.—ED.

In the next portion of the work, comprehending Chapters X. to XVIII., devoted to the description of the metals, Mr. Tidy has introduced some very useful tables, in which he gives, under the more important metals, lists of their salts, with the different acids, as well as the common and constitutional formulæ of the compound, and in many cases the molecular weight, specific gravity, and percentage of metal in the salt. This tabular form has not usually been systematically adopted in text-books, and has many advantages, more especially when the work is used for consultation.

In connection with this part, however, which embraces also the general consideration of acids, bases, and salts, it is to be regretted that the definition of an acid comes so late in the volume as p. 252; we should have expected to have found some description at least of an acid a little earlier. With respect also as to what "an acid is," the index of the work is misleading; thus, for instance, on consulting it with regard to the above point we are referred to p. 527, where we find the definition of an organic acid; the term acid in its ordinary sense being only found under the term salt. It may be urged that an acid is a salt of hydrogen, but it is rather too much to expect one who may be reading a chemical text-book for the first time to know all this, more especially as he meets with no explanation of the matter as far as we have found till p. 252.

The last part of the work, comprising Chapters XIX. to XXXI., is occupied with the consideration of the organic division of the science. We regret that space does not permit us to enter very fully into a review of this portion of the book, but as far as we can judge the information contained in it is accurate and well arranged. Here we are glad to see, as in the chapters describing the metals, tables giving the names, formulæ, specific gravities, boiling points, &c., of the different substances arranged in their respective groups or series. These tables we have no doubt will prove of very great use to the student. An appendix contains an account of the recent experiments of Pictet on the liquefaction of oxygen, &c., and a description of Mendeleeff's "Law of periodicity of the chemical elements." Great clearness in style is given to the book by the tables just referred to, and to the methodical manner in which Mr. Tidy has arranged the individual consideration of each element under several heads, as "(1) History, (2) Natural History, (3) Preparation, (4) Properties—(α) sensible, (β) physical, and (γ) chemical," and so on; but notwithstanding this arrangement, which adds to the value of the book, we regret the order in which the author has placed the non-metallic elements, which we cannot help regarding as defective in the case of a text-book designed for the use of students.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to ensure the appearance even of communications containing interesting and novel facts.*]

On the Proposed Observatory on the Summit of Mount Etna

Two years ago (September 22, 1876) Prof. Tacchini, of Palermo, read a paper before the Accademia Gioenia of Catania "Sulla Convenienza ed utilità di erigere sull' Etna una Stazione Astronomico-Meteorologica" (NATURE, vol. xv. p. 262). He proposed herein that an observatory should be erected at the Casa Inglesi, which is situated at the foot of the cone of the great crater 9,652 feet above the sea. In it daily observations, both astronomical and meteorological, should be taken during six months of the year, and the telescope should then be removed to Catania and the observations continued.

No more has been heard of this scheme but we sincerely trust that it will not fall to the ground, and that, if need be, our own astronomers will come forward to promote so good a work. No one who has not witnessed a cloudless starlit sky on a perfectly calm night from an elevation of two miles, can realise the difference between it and the same sky seen from the surface of the earth. When I ascended Etna in August, 1877, I was particularly struck by the extraordinary brilliancy of the midnight sky. It was one blaze of brilliant light. Myriads of stars which I had never seen before were visible, and the whole sky was studded with stars of every magnitude, colour, and brightness. The meteors which flashed across the sky were too numerous to count, and the stars themselves shone with extraordinary scintillations. I specially noticed a curious effect for which it is not easy to account, viz., the apparent lowness of the sky. It appeared to be almost pressing down upon one's head, and the larger stars seemed to be suspended below the sky. A good telescope brought to bear upon such a sky would reap a harvest of results. Tacchini noticed that Venus cast shadows, and Sirius appeared to rival Venus.

The observatory on Etna should be constructed on the most sheltered side of the mountain. It might be placed a little to the west of the Torre del Filosofo, the traditional observatory of Empedokles. It could be built of lava collected on the spot, and it would not be difficult to sink the foundations to a depth sufficient to ensure steadiness. It should be telegraphically connected with the observatory at Catania, and barometric and thermometric readings should be taken at the same instant of time at the two stations. It should be provided with a good 8 or 10-inch refractor, the lenses of which could be transported to a duplicate mounting in the observatory of Catania during the winter months. Moreover, it should possess a complete set of self-registering seismological instruments similar to those employed by Palmieri, and now exhibited in the Paris exhibition. Good spectroscopes should be provided, and a set of instruments for magnetic observations.

We are quite confident that considerable results would accrue to many of the sciences if systematic observations were carried out under the proposed conditions which have never yet been attempted, and we trust that astronomers both at home and abroad will not allow the subject to fall to the ground.

G. F. RODWELL

Compound Lightning Flashes

IN NATURE, vol. xviii. p. 67, an instance is given of several flashes of lightning following in the same path, and information concerning similar observations is asked for.

In almost every tropical thunderstorm the phenomena may be seen; to best advantage when the storm is distant. Three, four, and even more discharges may take place, the second and remaining flashes following in rapid succession through the identical path taken by the first. The intervals between the flashes vary; one may follow another so rapidly as to seem merely like a bright pulsation in the first, or there may be an appreciable interval of darkness; but it is certain that, if the eye can be trusted, these secondary flashes follow the exact course of their primary. The reason of this may be looked for in the heating effect of the lightning. The partial vacuum caused by the first discharge offers a line of comparatively small resistance to succeeding currents.

The singular part of the phenomenon is the rapidity with which the electricity must form or collect to admit of several discharges taking place at the same spot, for I do not think the secondary flashes can be regarded as merely residual.

During a severe storm at Mangalore on the 28th of last April two military buildings were struck by lightning, and, from the numerous paths taken by the electricity through the buildings, in its passage to the earth from the points struck, I was led to think the damage might be the result of these *compound* flashes; for it was conceivable that the destruction caused by each discharge might increase the resistance of the path taken, leaving succeeding flashes to follow in fresh directions of

less resistance. New lines might indeed be opened out by fragments of metal, such as nails, &c., scattered by the explosions.

In the case mentioned above, it was difficult, without some such theory, to account for the breaks in the courses followed by the electricity. E. H. PRINGLE

Bath, October 1

Gyno-Diœcious Plants

DURING the past summer I have found the following species in a gyno-diœcious condition, namely, *Ranunculus acris*, *R. repens*, *R. bulbosus*, and *Stachys germanica*, all of which have the corolla considerably reduced in size, and the stamens in *R. acris* and *S. germanica* either absent or reduced to scale-like bodies devoid of pollen. In *R. repens* and *R. bulbosus* the stamens are not so much reduced, but so far as I can judge they produced little or no pollen. The female form in *R. acris* is very common in Lancashire, but I failed to find any on the Lincolnshire coast although I searched carefully for it. In *R. repens* the female form is very rare, having seen only about thirty plants in all. I have also found the *Geum rivale* to be andro-monœcious. So far as I can ascertain these plants have not been noticed in the state described above.

Ashton-under-Lyne THOMAS WHITELEGGE

Wasps Under Chloroform

A FEW days ago a friend told me that she had often placed a bee under chloroform, and that the victims when they found they must die invariably brought their stings to their mouths and sucked the little drop of poison into their mouths. She offered to show me the experiment and endeavoured to catch a bee, but failing to do so she caught a wasp, an insect upon which she had not previously experimented in this way, and we both eagerly watched to see if the wasp would behave as the bees had done under the influence of the narcotic.

The wasp being put under an inverted tumbler in company with a piece of paper saturated with chloroform, in a very few seconds the insect fell on its back and almost immediately afterwards curled up the tail with the sting protruded and a drop of clear fluid on the end of the sting. The sting was brought to the mouth and the drop of fluid disappeared. The wasp then became motionless. After a few seconds the tumbler was removed and the air allowed to play freely on the insect, but no sign of life appeared, except once a slight twitch of the wing. To test whether the insect was really dead my friend placed it in a butterfly cage and left it out of doors all night. Next morning the wasp had disappeared; having perhaps crawled out by a little chink in the cage door.

Can you tell me whether so curious an action of these insects when subjected to chloroform is well known? Does it fulfil any good purpose? Is the poison a narcotic itself and taken by the insect to dull its pains when death seems inevitable? The revival of the wasp appears to show that neither the chloroform nor the poison of its own sting is deadly to the insect. W. M.

Clevedon, September 21

"Mercator" the Geographer

IN Prof. Huxley's "Physiography" it is stated that the real name of "Mercator," of "projection" fame, was Gerard Kauffmann. In a recent number, however, of the popular German journal, the *Gartenlaube*, there is a woodcut of Mercator, taken from an old sketch, under which is the legend—*Gerard Kremer genannt Mercator.* Now, as the word Kremer, or Krämer, means a small retail shopkeeper, the Latin pseudonym is equally applicable, although there is an appreciable difference, meaning excluded, between the two German surnames.

J. C. G.

Our Natural History Collections

IN your recent articles on "Our Natural History Collections," in which you criticised the Act of Parliament just passed authorising the removal of the natural history collections in the British Museum, I was surprised not to find any mention of the third clause, which inaugurates a new and enlightened policy in the disposal of duplicates. The clause was inserted at the instigation of Mr. A. J. Mundella, M.P., and Mr. J. Chamberlain, M.P., and is as follows:—"The trustees of the British Museum may also give away any duplicate works, objects, or specimens not required for the purposes of the museum, provided always that the powers hereby conferred shall not extend to any duplicate works in the royal library of King George IV., or in the Crackerode, Grenville, or Banksean libraries, or to any objects presented to the museum for use or preservation therein."

This important departure from the previous holdfast policy of the British Museum will be hailed with delight by all provincial students of natural history, as will also the paragraph in Prof. Sir C. Wyville Thomson's report to the British Association, referring to the disposal of the *Challenger* collections (*vide* NATURE, vol. xviii. p. 534).

Public museums are springing up all over the country, and any one acquainted with them knows well the difficulty of forming a natural history collection properly suited to educational requirements. If the power now conferred on the trustees of the British Museum is wisely and liberally used, I think as much material will be found stored away as will furnish provincial museums with the specimens required to make them educationally valuable. E. H.

Sheffield, September 26

OUR ASTRONOMICAL COLUMN

BIELA'S COMET.—The great swarm of meteors through which the earth passed on the evening of November 27, 1872, and which were found to be moving in the orbit of Biela's comet, must have been descending to a perihelion passage one month later, or about December 27·6 G.M.T. The comet not having been observed as such since the autumn of 1852, when both parts into which it was separated in 1846 were recovered, we may take this date as a new point of departure, assuming for the present that in following the great assemblage of meteoric bodies seen in November, 1872, we are following what now remains of the comet.

Hubbard's elements of the S. F. nucleus of 1852, with Michez's perturbations by Jupiter and Saturn, give the following elements for 1866, the latest year to which perturbations have been calculated:—

Perihelion Passage, 1866, January 27·6968 G.M.T.

	° ′ ″
Longitude of perihelion	109 39 48
,, ascending node	245 43 42
Inclination	12 22 3
Angle of eccentricity	48 46 19·4
Log. semi-axis major	0·5505333

We know that the comet did not arrive at perihelion at or near the above date in 1866, and hence that disturbance of its motion from an undiscovered cause must have taken place some time in the interval 1852–66. The period of revolution belonging to this orbit is 2445·67 days. There is no reason to suppose that the swarm of meteors is revolving in a shorter period, and we may consequently assume that it will not be again in perihelion before the date, which this period will give, if reckoned from December 27·6, 1872, or September 8, 1879; how much later the perihelion passage may fall it is impossible to foresee. We refer to this point on the present occasion with the view to suggest that a close watch for meteors of the Biela-comet stream should be instituted when the earth again passes the descending node of the comet's, orbit on November 27 next. With perihelion passage on September 8, 1879, the main cometary body would be in a true anomaly of $-135° 15'$. On December 6, 1798, when Brandes witnessed a great meteoric display, as the earth traversed the comet's orbit, it was in a true anomaly of about $-103°$, but in 1838, when under similar conditions meteors were observed in large numbers in Europe, Asia, and America, December 5–8, the comet's true anomaly was about $-128°$.

As regards the recovery of the comet in 1879, though perhaps not hopeless, a very strict examination of the

heavens in the neighbourhood of its projected track with considerable optical power may be necessary, and it will be particularly a case where the Astronomer-Royal's principle of mounting involved in his "orbit-sweeper" might be brought into useful requisition.

ENCKE'S COMET.—Mr. John Tebbutt, of Windsor, New South Wales, announces his re-observation of the comet of Encke, in the evening twilight on August 3, with the aid of the late Dr. von Asten's ephemeris, which had reached him on July 22. On August 5 it was pretty bright in a 4½-inch refractor, notwithstanding the moonlight, and Mr. Tebbutt hoped to secure a good series of positions. This comet has not passed unobserved at any appearance since its periodicity was discovered by Encke nearly sixty years ago.

BRORSEN'S COMET.—Prof. Schulze, of Döbeln, has published an ephemeris of Brorsen's comet of short period for the reappearance in 1879, founded upon a new discussion of the observations at the last two returns, and the application of the perturbations of Venus, the Earth, Mars, Jupiter, and Saturn. The comet will arrive at perihelion on March 30, and at its least distance from the earth on May 9, about which time its north declination will exceed 65°, so that it will be very favourably situated for observation in these latitudes. Prof. Schulze thinks the comet may be detected at the southern observations before the end of February.

NEW MINOR PLANETS.—Two new minor planets have been added to the list: the first detected by Prof. Peters, at Clinton, U.S., on September 18, the second by Prof. Watson, at Ann Arbor, on September 22—thus raising the number of known members of the group to 190.

AUGUSTUS HEINRICH PETERMANN

WE regret to record the sudden death, at Gotha, on September 26, of Dr. Augustus H. Petermann, one of the first cartographers of the present day. He was born at Bleicherode, in the neighbourhood of Nordhausen, Prussia, April 18, 1822. Although destined by his parents for the church, a pronounced taste for geographical study led to his entrance, at the age of seventeen, into the Geographische Kunstschule, founded shortly before at Potsdam, by Berghaus. Here, under the guidance of this famous geographer, he made rapid progress, and soon attracted the attention of leading *savants*. Among others Humboldt became interested in him, and entrusted him, when but nineteen years of age, with the preparation of the map accompanying his well-known work on Central Asia. Four years later, in 1845, he went to Edinburgh, in order to assist in the preparation of the English edition of the great Physical Atlas of Berghaus, issued by Johnston. Accompanying Petermann to Edinburgh was Henry Lange (now Dr. Lange, of the Berlin Statistical Bureau). These two, along with the late Keith Johnston, made an interesting tour through the Scottish Highlands, one result of which was a sketch or diagram of the Grampian range by Petermann, which he afterwards, we believe, published in London. In 1847 he settled in London, and was promptly elected into the Royal Geographical Society. His seven years' residence in London (1847-54) was one of continuous activity. Aside from the numerous maps which he executed, he contributed regularly to the *Athenæum* a *résumé* of the progress of geographical discovery, and issued, in union with Thomas Milner, an "Atlas of Physical Geography," and a fine folio atlas to illustrate Barth and Oberweg's travels in Africa. Two other maps which Petermann brought out during his stay in London still maintain their place on Stanford's list—a hydrographical and a population map of the British Islands. It was the publication of these maps, we believe, which enabled him to obtain the favourable notice of Baron Bunsen, who materially assisted Petermann in his progress. His connection with English publishers has always been close, and the last edition of the "Encyclopædia Brittanica" contains a number of admirable geographical articles from his pen. In 1855 he returned to his native land to take the management of Justus Perthes' Geographical Institute in Gotha, where an unlimited field was offered to his restless activity. In the same year he commenced the publication of the *Mittheilungen*, the successor of the *Geographisches Jahrbuch*, started by Berghaus. Under his careful editorship this periodical has become almost indispensable to those desiring to keep *au courant* with the progress of geographical discovery. No small portion of its rich and varied contents, as well as of its finely-executed maps, were due directly to Petermann. As cartographer Petermann was unwearied, and a constant succession of admirable maps have been executed by him during the past twenty-five years. Among these we might mention especially a great part of the magnificent collection forming Stieler's "Grosser Atlas," completed two years since; the map of the United States (1875), regarded by the government officials of that country as the most perfect extant; the maps accompanying the African travels of Barth and Rohlfs; and the lately-issued charts of the Arctic regions and the Turkish empire.

It is, however, chiefly by his criticism, his advice, and his enthusiastic, unwearied support of all attempts at geographical discovery, that Dr. Petermann has rendered his greatest services. Standing practically at the head of European geographers, the depositary of all that was being attempted or had been executed, esteemed and regarded by the authorities of the leading nations, he has enabled, by his personal efforts and wide-spread influence, many of our prominent explorers to find the necessary sinews of war, and successfully realise their plans of travel. Two great departments of geographical exploration have specially possessed his sympathies. The first was that of Arctic exploration, and dates from the interest excited during his residence in England, by the expeditions sent forth in search of Franklin. It was almost entirely due to his exertions that the German government equipped the successive expeditions of Werner (1865), Koldewey (1868), and Koldewey and Hegemann (1869), all of which aimed at the exploration of the east coast of Greenland—Petermann's favourite route for approaching the Pole. His advice was likewise of material assistance in the preparations for the late Austrian, English, Dutch, and Swedish expeditions, and few voyages to the icy regions have been undertaken of late years without consultation with Petermann on the general plan.

A still deeper interest was shown by him in the matter of African travel. The important expedition of Barth, Overweg, and Vogel, in 1849, was instituted by the Prussian Government, chiefly on the recommendations of Bunsen and Petermann. Heuglin's and Munzinger's expedition in 1861 was also due entirely to his instigation. Rohlfs' journey in Morocco, as well as Mauch's expedition in South Africa, would have been impossible without his assistance, and his name is closely associated with the important expeditions of Schweinfurth and Nachtigal.

The numerous contributions of Petermann to geographical literature are contained in the *Mittheilungen*, with the exception of those published in English. Of late years he has occupied the chair of geography at the Gotha Polytechnic.

As we have said, the *Geographische Mittheilungen* has become indispensable to all who wish to keep pace with the progress of geography; and from its pages a fair idea may be obtained of the all-comprehensiveness of that department of knowledge. We are glad to learn, from a circular signed by Dr. Behm, the efficient colleague of Petermann, that this *facile princeps* of geographical

journals is to be continued. We trust its comprehensiveness, thoroughly scientific character, and general high standing will be maintained, and that it will continue a permanent monument to the genius, knowledge, and zeal of its founder.

THE NORWEGIAN NORTH ATLANTIC EXPEDITION

THE *Vöringen* left Hammerfest on July 29 on its last cruise. On the 31st, at noon, Bear Island was reached. Here the expedition was kept till August 3, the weather being too stormy to allow sea work to be done. In the night of August 1-2 a party landed on the east side of the island, where the sea was sufficiently smooth to allow a boat to land: but foggy weather interfered with any observations of importance being made. Some birds were shot and some fossils collected. In the morning hours extensive fishing operations were carried on from the deck of the ship, now anchored in some 12 fathoms. From 4 to 7 A.M. 200 large cods were hauled. From a point about midway between Bear Island and Spitzbergen we worked first up a cross section towards west-north-west, till we found 1,149 fathoms' depth on the afternoon of the 4th. From this point the course was shaped for South Cape, Spitzbergen. At noon on the 5th we made the cape, sailed round the island lying off the cape, and entered the Stor-Fjord. Here the sun was shining and the water smooth, so Capt. Wille swung the ship for deviation. The next morning we dredged on the bank lying south-east of South Cape; here the temperature was $-1^{\circ}\cdot 2$ C. at the bottom, in 140 fathoms, and zero in 120 fathoms. In the upper layers the temperature was very irregularly distributed, both increasing and decreasing with depth. We went again round the islands and to the west side of South Cape, taking here a departure for a larger cross section along the parallel of the cape towards Greenland. Having crossed the Spitzbergen bank, we sounded 523, 743, 1,017, 1,429, 1,487, and 1,686 fathoms, when we at last, on August 8, were stopped by the ice in 76° 26′ N. lat. and 0° 29′ W. long. Off the Spitzbergen bank we found 0° C. in a depth of 470 fathoms. The polar current was reached in long. 5° E. Station No. 360, where we met the ice, gave the following serial temperatures characteristic of the polar current:—Surface, $3^{\circ}\cdot 2$ C., 40 fathoms, $-1^{\circ}\cdot 3$; 70 fathoms, $-0^{\circ}\cdot 3$; 200 fathoms, $-0^{\circ}\cdot 7$; 300 fathoms, $-1^{\circ}\cdot 0$; 1,686 fathoms at bottom, $-1^{\circ}\cdot 3$. On this station we lost a trawl and 2,163 fathoms of dredge rope. The sea-bottom between Spitzbergen and Greenland was very rough; the trawl or dredge seldom came up without damage or having stones inclosed, some of which were rather heavy. We sailed, on August 9, northwards along the ice, and reached our next cross section on the 10th, lat. 77° 50′, long. 0° 9′ W. The soundings were, from west to east, 1,640, 1,686, 1,333, 1,343, 948, 110 fathoms. The polar current closed in about 4° E. long. Farther east, 0° C. was found in 300 to almost 500 fathoms. On Station No. 354, lat. 78° 1′, long. 6° 54′ E., we had the great satisfaction of verifying the Swedish sounding made in 1868 at the same place by von Otter in the *Sofia*. The Swedes found 1,350 fathoms, we found 1,343. This agreement gives me great confidence in von Otter's soundings, which were made with less perfect means than ours. The Swedish deep-sea soundings in the *Sofia* extend far westwards and northwards from Spitzbergen, and are therefore of the greatest importance. From our last cross-section we took a longitudinal section parallel to the coast of Spitzbergen. The depths reached were 421 fathoms (temperature $0^{\circ}\cdot 0$), 905 fathoms, and 459 fathoms in lat. 79° 59′, long. 5° 40′ E. There was 0° in 390 fathoms depth. There was ice floating in the surface temperature at $5^{\circ}\cdot 2$. This brought our section to a close.

It appears that here on the 80th parallel, the warm Atlantic current is still running northwards, backed up on the west coast of Spitzbergen. The polar ice, driven by northerly winds, is swimming on its back, and melted gradually off just like the end of the glaciers in the summer heat of the valleys. It was apparent that the current was rather strong towards the north, the ship's place being always, by observations and bearings, found more northerly than by dead reckoning. On the open sea it was found very difficult, not to say impossible, to determine the ship's place with the ordinary accuracy. The horizon was generally—as we observed when off the shore—lifted by a sort of mirage.

On August 15 we dropped our anchor at the Norway Islands, North Spitzbergen, where we took in some ballast. In the sound, where we were lying, the beach was formed of mere loose stones, granite, apparently burst asunder by frost. Flakes and small bergs of ice sailed through the sound with the tide and were often touching the shore, but I could not observe there any sign of the ice cutting any line or mark along the beach. From the Norway Islands we went out off Hackluyt Head, where we took a sounding, passed the Smeerenberg and the South Gat, and anchored in Magdalena Bay. The Admiralty chart of the last-named places, surveyed in 1818 by Franklin and Beechy, proved very accurate. In Magdalena Bay we found a bottom temperature of $-1^{\circ}\cdot 7$ to $-2^{\circ}\cdot 0$, in exact agreement with the results formed by M. Charles Martins in 1839 in the *La Recherche* expedition. Our last visit was in the Advent Bay ice-fjord, where Capt. Wille constructed a chart of the bay, assisted by Capt. Grieg and myself, who measured the base line, some trigonometrical angles, and took altitudes for latitude and longitude. Foggy weather prevented our visit to Bell Sound. On August 23 we left Spitzbergen, and on the 26th we anchored at Tromsö. On September 4 the *Vöringen* returned to Bergen and the expedition was closed. The three summers have yielded in all 375 sounding-stations, 113 temperature series, 44 dredgings, and 42 trawlings.

H. MOHN

THE ANCIENT CAPITAL OF ITHACA

IN a recent letter to the *Times* Dr. Schliemann describes his search for the ancient capital of the island of Ithaca. He began his researches in the valley called Polis, which is in the northern part of the island, and has generally been considered as the site of the Homeric capital of Ithaca—first, on account of its name, which is the Greek word for city; second, on account of its splendid harbour, at a distance of only two miles from a small island now called Mathitarió, which, being the only one in the strait between Ithaca and Cephalonia, has naturally always been identified with the Homeric island of Asteris, behind which the suitors of Penelope were in wait for Telemachus on his return from Pylos and Sparta ("Odyssey," iv., 844-847). As a fourth reason for the identity of Polis with the site of Ithaca's capital, he mentions an acropolis which one thinks to perceive on the very steep rock, at a height of about 400 feet, on the north side of the port. Dr. Schliemann found it to consist of a very irregular calcareous rock, which had evidently never been touched by the hands of man, and can most certainly never have served as a work of defence. There can be no doubt that the name of this valley is derived not, as has been hitherto thought, from a real city, but merely from an imaginary fortress.

Besides, this valley is the most fertile spot in Ithaca, and it can therefore never have been used for the site of a city; in fact, it never yet occurred in Greece that a city should have been built on fertile land, and least of all can such have been the case on the rocky island of Ithaca, where arable land is so exceedingly rare and precious.

The island Mathitarió Dr. Schliemann visited and carefully measured. Its length is 586 feet; its breadth varies between 108 feet and 176 feet. It cannot, on account of these small dimensions, possibly be identified with the Homeric Asteris, which, as the poet says, had two ports, each of them with two entrances.

Though for all these reasons Dr. Schliemann was perfectly convinced that no city can ever have occupied the fertile valley of Polis, yet he thought it in the interest of science to investigate the matter by actual excavations. He sunk there many shafts, but in nearly all of them he struck the natural rock in a depth of 10 to 13 feet, except in the middle of the valley, which seems to have been hollowed out to a great depth by a mountain torrent. Fragments of rudely-made black or white Greek pottery and pieces of tiles were all he found. There were only a few fragments of archaic pottery for which he could claim the sixth century B.C. Tombs are sometimes found on the neighbouring heights, but, as is proved by the pottery and coins contained in them, they are of the third, fourth, or fifth century B.C. Of the same period are also the antiquities found in a cavern to the right of the port of Polis; for an inscription found there Dr. Schliemann can with certainty claim the sixth or even the seventh century B.C. Therefore, the supposition that Polis is the site of the Homeric capital of Ithaca must now be definitely abandoned.

Dr. Schliemann afterwards carefully surveyed the remaining northern part of the island, but found nowhere the site of an ancient town, except in the environs of the small building of cyclopean masonry, usually called "School of Homer," which the owner of the property has lately converted into a small church. He refused Dr. Schliemann permission to excavate in the church, but allowed him to do so in the adjoining fields, where a number of rock-cut house foundations and remnants of cyclopean walls testified to the existence of an ancient settlement. He dug there a great many holes, but always struck the natural rock in less than 3 feet, and sometimes even in a depth of less than 12 inches; thus there can be no doubt that a town has existed here in classical times, and most probably it is the very town mentioned by Scylax Per. 34, and Ptolemæus III., 14, 13.

Dr. Schliemann proceeded thence to Mount Aetos, situated on the narrow isthmus, hardly one mile wide, which joins northern and southern Ithaca. He found everywhere the purest virgin soil, except on the very crest of the ridge, where, near the chapel of Hagios Georgios, he found a very small plain with an accumulation of artificial soil 10 feet deep. He dug there two long trenches, in one of which he brought to light a terrace-wall 7 feet high, consisting of huge polygonal blocks, well fitted together; to compare this wall to the modern terrace-walls which surround it is to compare a giant's work to a work of dwarfs. Of pottery he found there nothing but a few fragments of black Greek vases. Having here also failed in his researches he most carefully explored Mount Aetos, which rises to the height of 1,200 feet from the sea, and has on its artificially, but rudely, levelled summit a platform of triangular form, with two large cisterns and a small one, and remnants of six or seven small cyclopean buildings, which were either separate houses or—and more probably—chambers of the large cyclopean mansion which is said to have stood there, and is commonly called "the Castle of Ulysses." There can hardly be any doubt that the level summit of Mount Aetos was extended to the north and south-west by a huge cyclopean wall still existing, the space between the top and the wall being filled up with stones and *débris*. Thus the summit forms a quadrangular, even platform 166 feet 8 inches long by 127 feet 4 inches broad, so that there was on the summit ample room for a large mansion and a courtyard. To the north and south of the circuit-wall are towers of cyclopean masonry, from each of which a huge wall of immense boulders runs down. But at a certain distance these two walls begin to form a curve, and ultimately join together. Two more cyclopean walls run down from the top—the one in an easterly, the other in a south-easterly direction, and join the curve formed by the two first-named walls. Lastly, he mentions a huge circuit-wall about 50 feet below the upper circuit-wall. This wall has fallen on the west side, but is in a marvellous state of preservation on the other sides. To increase the strength of the place the foot of the rock has been cut away so as to form a perpendicular rock wall 20 ft. high. In the walls are recognisable three gates. Between all those cyclopean walls once stood a city, which may have contained 2,000 houses, either cut out in the rock or built of cyclopean masonry. Of 190 of these houses Dr. Schliemann has been able to find the ruins more or less well preserved. He measured twelve of them and found them between 21 feet and 63 feet long, and 15 feet to 20 feet broad. The usual size of the rudely cut stones is 5 feet in length, 4 feet 8 inches in breadth, and 2 feet in thickness. The size of these stones by far exceeds that of the stones in the cyclopean houses Dr. Schliemann discovered at Mycenæ and Tiryns. Some of the houses consisted of only one room, others had four or even six chambers. This cyclopean capital is unique in the world, and every admirer of Homer ought to see it.

For two weeks Dr. Schliemann excavated with thirty workmen in those cyclopean buildings; but fragments of pottery, which has no resemblance to any of the Mycenæan pottery, but is much like that from the two most ancient cities at Troy; fragments of most curious tiles with impressed ornaments; also two with a sort of written characters which he has not yet had time to copy; further, the fragments of a most curious handmill—wer the only result of all his labour.

Dr. Schliemann has also commenced excavating the stalactite grotto near the little port of Dexia, which is generally identified with the port of Phorkys, where Ulysses was landed by the Phæacians, the grotto being rightly considered to be identical with the Homeric grotto of the Nymphs, in which Ulysses, assisted by Minerva, hid his treasures. But having opened a trench just before the little altar, down to the rock, without even finding a potsherd, he abandoned this ungrateful excavation. The grotto is very spacious, and it exactly answers the description of Homer, who says "that it has two entrances, one on its north side for men, and one on its south side for the immortal gods, for no man can enter by the divine door." All this is true, but by the entrance for the gods he means the artificially cut hole in the vault of the grotto, which must have served as a chimney to lead off the smoke of the sacrificial fires. From this chimney to the bottom of the grotto is 56 feet, and, of course, no man can enter by this way. From the vault of the grotto hang innumerable stalactites, which have given to Homer the idea of the stone urns and amphoras, and the stone frames and looms on which the Nymphs weave purple-coloured mantles and veils. Dr. Schliemann most carefully explored the whole southern portion of Ithaca. The town of Vathy, the present capital of Ithaca, is not yet a hundred years old, and the complete absence of ancient potsherds on the flat soil seems to prove that there has been no city or village on the site in antiquity. Before Vathy was founded the city was on a rocky height about one mile further south. On the site of the old town he found but a very small accumulation of *débris*, and no trace of ancient pottery.

Near the south-east extremity of the island, about 4½ miles from Vathy, are a number of stable-like rooms, averaging 25 feet in length and 10 feet in breadth, partly rock cut, partly formed by cyclopean walls of very huge stones, in which Homer must have seen the twelve swine stables built by the divine swine-herd Eumæus. To the east of these stables and just in front of them, thousands

of very common but most ancient potsherds indicate the existence of an ancient rustic habitation, which Homer appears to have described to us as the house and station of Eumæus. This is the more probable as at a very short distance to east of this site, and near the sea, is a white cliff with a perpendicular descent of 100 feet which until now is called Korax—*i.e.*, the Raven Rock, to which Homer refers when he represents Ulysses as challenging Eumæus "to precipitate him from the great rock" if he finds that he is telling lies (Od. xiv. 398). Below the Korax, in a recess, is natural and always plentiful pure water, which the tradition identifies with Homer's fountain of Arethusa, from which Eumæus's swine were watered. Dr. Schliemann excavated as well in the stables as in front of them on the site of the rustic habitation; the stable he found filled with stones, but on the site of the house he struck the rock in a depth of one foot, and found there fragments of very interesting, most ancient, unpainted pottery, also of pottery with red bands, and masses of broken tiles.

Dr. Schliemann states that Ithaca is, like Utica, a Phœnician word, and means "colony," and that the type of the Ithacans is decidedly Phœnician. According to Homer Laertes's grandfather was Poseidon, and Mr. Gladstone is therefore perfectly right that the descent from Poseidon always means "descent from the Phœnicians."

Dr. Schliemann has obtained a new firman for Troy. He left Athens on September 18 for the Troad to continue his long interrupted excavation of Troy. His first work will be to bring to light the whole of the mansion immediately to the north and north-west of the gate, which seems to belong to the ancient city's chief or king.

ARE THE "ELEMENTS" ELEMENTARY?[1]

THE problem set before us by the words which I have chosen as a heading for this article is a vast one; unfortunately the data upon which an answer must be founded are in themselves vague and meagre. It is useless attempting to draw an exact conclusion from inexact data. If the degree of probability which attaches itself to the data is small, the probability of the conclusion being true must be yet smaller.

In the times of the ancients men do not appear to have attached any very definite idea to the word "Element." An element was a something, a material or an imaginary something—it did not very much matter which—a something which one might suppose, if one were so minded, to form a sub-stratum upon which other, apparently more complex, things rested. Fire was an element; it was supposed to enter into the constitution of matter of many kinds. Some people said they believed that fire and water formed earth of different kinds; others averred that air and water were the foundations of all things. But it was perfectly legitimate for a third person to tell the two former that they were completely in error, that *really* sulphur and salt were the primary elements, and that from these all other forms of matter arose.

No exact data concerning the possibility of transforming earth into air, or water into fire, or salt into sulphur were forthcoming. Men did not generally trouble themselves with investigations into the actual properties of the so-called elements. Everything was founded on supposition; the human mind was superior to nature, and could project itself upon nature and explain nature.

Such a method could lead to no true knowledge of natural phenomena. To-day we have altered our method of investigation. Nature presents us with a mass of materials; most of these we can decompose into two or more forms of matter, but some of these resist all efforts hitherto made to effect their analysis. The latter we call elements, the former compounds. Our knowledge is imperfect; we acknowledge the imperfection, but attempt to make the knowledge *exact so far as it goes*. Whether the so-called elements are or are not capable of further subdivision is an open question. Whatever answer this question may finally receive, the superstructure of chemical science will remain unshaken. We may find it necessary to alter the form of many statements; the facts and, I am persuaded, many of the theories, will remain.

An element is then a substance which has hitherto yielded no simpler form of matter than itself. We make the hypothesis that matter is built up or compounded of those substances which we call elements. But this is of course only an hypothesis. So long as we accept it as such it is of the utmost service to us; whenever we erect it into a dogma it ceases to become an aid to the investigation of nature, and begins to exercise a tyranny over us.

An amusing and instructive instance of the narrowing and deadening effect of accepting an hypothesis dogmatically is narrated in Prof. Bryce's recently-published book on Trans-Caucasia. Prof. Bryce accomplished the ascent of Mount Ararat: tradition says that no one has ever been to the summit of this mountain; the inhabitants of the neighbouring country have formed this saying into a dogma which teaches that no one can ascend to the top of Ararat. When Prof. Bryce told the Archimandrite of the district that he had been to the summit the old man only smiled a sweet, sad, pitying smile, and said it was impossible.

The more modern history of the chemical elements warns us against dogmatising concerning the nature of these bodies. Potash and soda were classed among the elements until the year 1807. Water was for ages regarded as elementary; Cavendish first taught us that the long-cherished tradition was false.

The problem of the nature of the elements is one which requires the use of the imagination; it is a problem in endeavouring to solve which we are very ready to give the reins to this faculty, or rather to allow the lower power of fancy to usurp the place of the more divine imagination—and thus we run riot. The naturalist who approaches the investigation presented by the chemical elements had need to learn the scientific use of the imagination.

Many years ago an hypothesis was started by Prout to the effect that the elements are all compounds of hydrogen, that hydrogen is the primary form of matter, and that the molecule of each element is composed of a varying number of atoms of hydrogen. If this hypothesis were correct the combining or atomic weights of the elements would be simple multiples of the combining or atomic weight of hydrogen, *i.e.*, multiples of 1. The experiments of Dumas lent support to the hypothesis of Prout, but the later and more exact researches of Stas negatived the idea.

Stas showed, in a wonderful series of investigations, that the atomic weights of the elements are not simple multiples of 1, nor of $\frac{1}{2}$, as Dumas had supposed, but that they are fractional numbers. Stas further showed that the same number, as representing the atomic weight of a given element, is obtained by different processes of investigation.

But may not Prout's hypothesis have some truth underlying it? Are the elements really elementary? Stas's researches do not answer this question. We may put the general question in two forms. Are the elements compounds, in varying proportions, of a few simple bodies? or, Are the elements compounds, in varying proportions, of *one* primary form of matter? Let us look at these questions in succession—and first we may frame the hypothesis that the elements are compounds of a few simple bodies.

In order to learn what are the general properties exhibited by a series of bodies all of which are compounds,

[1] A paper read before the Owens College Chemical Society.

in varying proportions, of a few simple bodies, let us consider one of the homologous series of hydrocarbons; say the marsh-gas series. CH_4, C_2H_6, C_3H_8, C_4H_{10}, C_5H_{12}, C_6H_{14}, &c., &c.; generally C_nH_{2n+2}. The members of this series are all compounds, in varying proportions, of carbon and hydrogen; each differs from the preceding by an increment of CH_2. The difference between the molecular weights (the weights of two vols.) of the members of the series is 14. The physical properties of the series show a gradation from the first upwards. The first is gaseous at ordinary temperatures: as we ascend the series we have liquids of gradually-diminishing liquidity, then solids, the melting-points of which gradually increase. The chemical properties of the series, so far as these have been investigated, also exhibit a regular gradation. If we divide the specific heats of these compounds by their molecular weights, we do not obtain the same number for each—in other words, the molecular heat of the members of this series varies: this is a point of some importance. The specific volumes —products obtained by dividing molecular weights by specific gravities determined at that point at which each vapour exerts the same tension, that is, at the boiling points of the liquids—of the members of this series differ by 22. A simple relation of some kind most probably exists between the densities of the members of this series, between the actions exerted by these bodies on light, &c., &c.

Take now a group of allied elements:—Oxygen (16), sulphur (32), selenium (79·5), tellurium (128). The atomic weights—or the molecular weights, whichever form is preferred—of the higher members of the series are multiples of the atomic weight of the first: $16 \times 2 = 32$, $16 \times 5 = 80$; $16 \times 8 = 128$. Oxygen is a gas, except under conditions of great pressure; sulphur melts at about 115°, selenium at about 100°, but a modification at 215°; tellurium at 450° C. There is a gradation in the general chemical nature of the four elements. There is a simple relation between the specific volumes of these four elements in the solid state; this relation is expressed by the numbers 1 : 3 : 3 : 4. The atomic heats of the three last-named substances are the same; the atomic heat of solid oxygen, as deduced from observations carried out on compounds, is rather less than the number representing the atomic heats of sulphur, selenium, and tellurium. I might adduce other series of elements, let one suffice:—

	Lithium.	Sodium.	Potassium.	Potassium.	Rubidium.	Cæsium.
Atomic weight =	7	23	39·1	39·1	85·4	133
Mean ,, =	—	23·05	—	—	86·05	—

The atomic weight of the second member of each sub-section of this series is almost exactly the mean of the atomic weights of the first and third; in each case the number representing the atomic weight of the middle element is a very little less than the mean of the atomic weights of the elements at the extremes of the series. The specific volumes of the metals lithium, sodium, potassium, and rubidium (the specific gravity of cæsium is unknown) are respectively, 11·9, 23·7, 45·1, and 56·2; these numbers are nearly in the proportion of 1 : 2 : 4 : 5; there is a regular gradation, therefore, in the specific volumes of the members of the present series. The physical and chemical properties of the series show gradations, which, so far as they have been examined, appear capable of tolerably simple generalisation. The atomic heat of the five metals is represented by a (practically) constant number. Now most of these facts are quite in keeping with the hypothesis that the elements which I have noticed are compounds of simpler forms; the properties of the compounds of the homologous series, C_nH_{2n+2}, are in very many respects analogous with the properties of the two series of so-called elements to which I have drawn attention. There is, however, one important difference between a certain physical property of the homologous series and the same property as exhibited in the elementary series—the atomic or molecular heats of the elements are, with few exceptions, the same; the numbers expressing the molecular heats of the members of the homologous hydrocarbon series are multiples of each other.

"It seems a general law," says Berthelot, "that the molecular heats of polymerised radicles are multiples of each other, whereas the molecular heats of the elements are, with very few exceptions, identical." The apparent exceptions among the elements, we have good reason to believe, will be found to obey the rule when more exact investigations have been carried out. This difference between the molecular heats of the elements and the molecular heats of series of homologous hydrocarbons lessens the probability of the elements being really compounds, in varying proportions, of a few simple bodies; or at any rate, it leads us to believe that, as Berthelot says, the phenomena attending the decomposition of the elements—supposing them to be really compounds—must be different from the phenomena attending the decomposition of those bodies which we know to be compounds. Nevertheless, I think that too much weight may be attached to this fact of differences in molecular heats. We do know of many compound gases, gases in the formation of which a very considerable amount of condensation occurs, but which have almost identical molecular heats. We have whole series of similarly constituted groups of compounds having the same molecular heats, *i.e.*, provided we accept the ordinary formulæ for solid compounds as molecular formulæ. So that the mere fact that the elements have the same molecular heats need not, I think, be a bar in the way of regarding these bodies as compounds, provided we have other evidence pointing in that direction.

But I must now briefly consider the second form under which the general question of the nature of the elements presents itself, viz., are the elements compounds, in varying proportions, of *one* primary form of matter? As a matter of fact we know of compounds in varying proportions of the same elements; we know also of compounds in varying proportions of one and the same element. The facts which have been amassed concerning allotropy and isomerism must be of service in any attempt which may be made to answer the question we are now to consider.

It is generally possible to trace a simple relation between the specific volumes $\left(\frac{\text{mol. wt.}}{\text{Sp. Gr.}}\right)$ of the various members of a group of elements; we have seen that such a relation exists in the two groups already considered, viz., the oxygen group and the potassium group. But it is stated by F. W. Clarke, of Cincinnati, who has partially investigated this subject of specific volumes, that so far as experiment has gone, no simple relation can be traced between the specific volumes of allotropic modifications of one and the same element. This statement appears to me to assume an amount of knowledge which we really do not possess. Clarke finds for the specific volume of ordinary sulphur the numbers 10·4 and 15·6; for prismatic sulphur he finds a number varying from 16·3 to 16·7; there is no simple relation between this number and either of the former. But he has assumed that the atomic weight of each allotrope is the same, and we have no data warranting such an assumption; the knowledge which we do possess points rather to an opposite conclusion. I think I am right in saying that in the case of oxygen and ozone we do possess some accurate knowledge of the (relative) molecular weights of two allotropes; these molecular weights are different; hence, probably, the atomic weights of the allotropes are also different.

ON THE NATURE OF VIBRATORY MOTIONS[1]

II.

Blackburn's Double Pendulum.

EXPERIMENT 7.—Let us return to our sand-pendulum. We have examined the vibrations of a single pendulum, let us now examine the vibrations of a double pendulum, giving two vibrations at once. The little copper ring *r*, in Fig. 7, on the cord of our pendulum, will slip up and down, and by moving it in either direction we can combine two pendulums in one. Slide it one quarter way up the cord, and the double cord will be drawn together below the ring. Now, if we pull the bob to the right or left, we can make it swing from the copper ring just as if this point were a new place of support for a new pendulum. As it swings, you observe that the two cords above the ring are at rest. But the upper pendulum can also be made to swing forward and backward, and then we shall have two pendulums combined. Let us try this and see what will be the result.

Just here we shall find it more convenient to use the metric measure, as it is much more simple and easy to

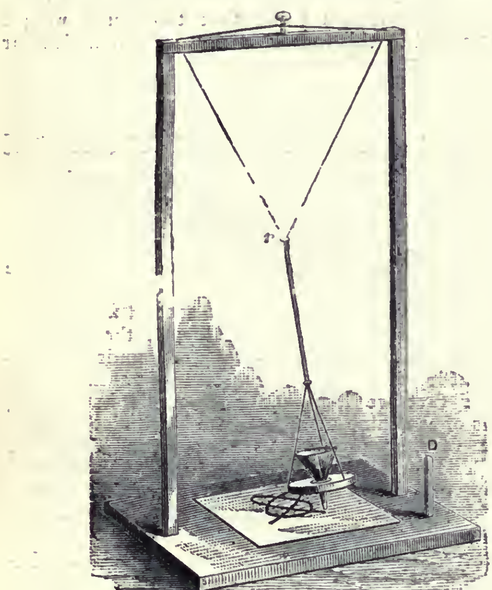

FIG. 7.

remember than the common measure of feet and inches. If you have no metric measure you had best buy one, or make one. Get a wooden rod just $39\frac{37}{100}$ inches long, and divide this length into 100 parts. To assist you in this you may remember that 1 inch is equal to $25\frac{4}{10}$ millimetres. Ten millimetres make a centimetre, and 100 centimetres make a metre.

Now slide the ring *r*, Fig. 7, up the cords till it is 25 centimetres from the middle of the thickness of the bob. Then make it exactly 100 centimetres from the under side of the cross-bar to the middle of the thickness of the bob, by turning the violin-key on the top of the apparatus.

At D, Fig. 7, is a small post. This post is set up anywhere on a line drawn from the centre of the platform, and making an angle of 45° with a line drawn from one upright to the other. Fasten a bit of thread to the string on the bob that is nearest to the post, and draw the bob toward the post and fasten it there. When the bob is perfectly still fill the funnel with sand, and then hold a lighted match under the thread. The thread will burn, and the bob will start off on its journey. Now, in place of swinging in a straight line, it follows a curve, and the sand traces this figure over and over.

FIG. 8.

Here we have a most singular result, and we may well pause and study it out. You can readily see that we have here two pendulums. One-quarter of the pendulum swings from the copper ring, and, at the same time, the whole pendulum swings from the cross-bar. The bob cannot move in two directions at the same time, so it makes a compromise and follows a new path that is made up of the two directions.

The most important fact that has been discovered in relation to the movements of vibrating pendulums is that the times of their vibrations vary as the square roots of their lengths. The short pendulum above the ring is 25 centimetres long, or one-quarter of the length of the longer pendulum, and, according to this rule, it moves twice as fast. The two pendulums swing, one 25 centimetres and the other 100 centimetres long, yet one really moves twice as fast as the other. While the long pendulum is making one vibration the short one makes two. The times of their vibrations, therefore, stand as 1 is to 2, or, expressed in another way, 1 : 2.

Experiment 8.—Let us try other proportions and see what the double pendulum will trace. Suppose we wish one pendulum to make 2 vibrations while the other makes 3. Still keeping the middle of the bob at 100 centimetres from the cross-bar, let us see where the ring must be placed. The square of 2 is 4, and the square of 3 is 9. Hence the two pendulums of the double pendulum must have lengths as 4 is to 9. But the longer pendulum is always 1,000 millimetres. Hence the shorter pendulum will be found by the proportion 9 : 4 : : 1,000 : 444·4 millimetres. Therefore we must slide the ring up the cord till it is 444·4 millimetres above the middle of the thickness of the bob.

Fasten the bob to the post as before, fill it with sand, and burn the thread, and the swinging bob will make this singular figure (Fig. 9).

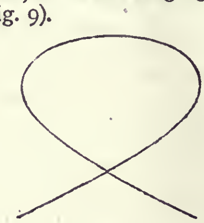

FIG. 9.

Experiment 9.—From these directions you can go on and try all the simple ratios, such as 3 : 4, 4 : 5, 5 : 6, 6 : 7, 7 : 8, and 8 : 9. In each case raise the two figures to their squares, then multiply the larger number by 1,000, and divide the product by the smaller number; the quotient will give you the length of the smaller pendulum in millimetres. Thus the length for rates of vibration, as 3 is to 4, is found as follows: $3 \times 3 = 9$, $4 \times 4 = 16$, and $\frac{9 \times 1{,}000}{16} = 562{\cdot}5$ millimetres.

The table (Fig. 10) gives, in the first and second columns, the rates of vibration, and in the third and

[1] From a forthcoming work on "Sound: a Series of Simple, Entertaining, and Inexpensive Experiments in the Phenomena of Sound, for the Use of Students of every Age." By Alfred Marshall Mayer, Professor of Physics in the Stevens Institute of Technology. Communicated by the Author. (Continued from p. 574)

fourth columns the corresponding lengths of the longer and shorter pendulums. Opposite these lengths are the figures which these double pendulums trace. In the sixth column are the names of the musical intervals formed by two notes, which are made by numbers of sonorous vibrations, bearing to each other the ratios given in the first and second columns.

	Mm.	Mm.	
1 : 2 =	1,000 :	250·0.........	Octave.
2 : 3 =	1,000 :	444·4.........	Fifth.

7 : 8 =	1,000 :	766·6.........	Super Second.
8 : 9 =	1,000 :	790·1.........	Second.

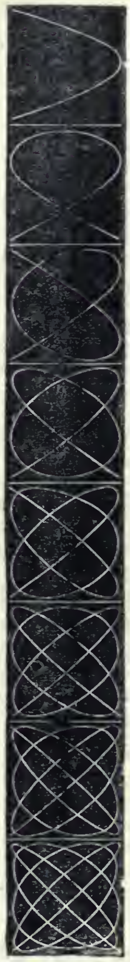

Fig. 10.

Prof. Kundt's Experiment, made with a Whistle and a Lamp Chimney, showing that, as in Wind Instruments, a vibrating Column of Air may originate Sonorous Vibrations.

Experiment 10.—The chimneys of student-lamps have a fashion of breaking just at the thin, narrow part near the bottom. Such a broken chimney is very useful in our experiments. At A, in Fig. 11, is such a broken chimney, closed at the broken end with wax. A cork is fitted to the other end of the chimney, and has a hole bored through its centre. In this hole is inserted part of a common wooden whistle. At B is an exact representation of such a whistle, and the cross-line at C shows where it is to be cut in two. Only the upper part is used, and this is tightly fitted into the cork.

Inside the tube is a small quantity of very fine precipitated silica, probably the lightest powder known. Hold the tube in a horizontal position and blow the whistle. The silica powder springs up into groups of thin vertical plates, separated by spots of powder at rest, as in the figure. This is a very beautiful and striking experiment.

Experiment 11.—The following experiment shows that the sound is caused by the vibrations of the column of air in the tube and whistle, and not by the vibrations of these solid bodies. Grasp the tube and whistle tightly in the hands. These bodies are thus prevented from vibrating, yet the sound remains the same.

The breath driven through the mouth of the whistle strikes on the sharp edge of the opening at the side of the whistle, and sets up a flutter or vibration of air. The air within the glass tube now takes part in the vibrations, the light silica powder vibrates with it, and makes the vibrations visible.

To exhibit this experiment before a number of people, lay the tube carefully on the water-lantern before the heliostat, and throw a projection of the tube and the powder on the screen. When the whistle is sounded, all in the room can see the fine powder leaping up in the tube into thin, upright plates.

Experiment 12.—Mr. Geyer has made the following

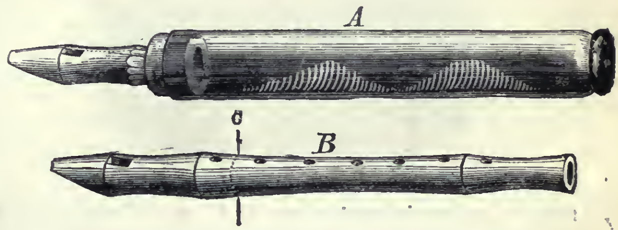

Fig. 11.

pleasing modification of this experiment:—Take a glass tube about 2 feet (61 centimetres) long and ¾ inch (19 millimetres) diameter. One end of this tube is stopped with a cork; then some silica is poured into it. The other end is placed in the mouth. Singing into the tube, a note is soon struck which causes the silica to raise itself in groups of vertical plates, separated by places where the powder is at rest, the number of these groups and their positions in the tube changing with the note sung.

We have now seen how solids, like steel or brass, may vibrate and give a sound. We have heard a musical sound from vibrating water, and these last experiments prove that a gas, like air, may also vibrate and give a sound. In the next chapter you will find experiments which show how these vibrations move through solids, through liquids, and through the air.

On the Interference of Sonorous Vibrations and on the Beats of Sound.

Experiment 13.—Cut out two small triangles of copper foil or tinsel, of the same size, and with wax fasten one on the end of each of the prongs of a tuning-fork. Put the fork in the wooden block and set up the guide. Prepare a strip of smoked glass, and then make the fork vibrate and slide the glass under it, and get two traces, one from each prong.

Holding the glass up to the light you will see the double trace, as shown in Fig. 12. You observe that the

Fig. 12.

wavy lines move apart and then draw together. This shows us that the two prongs, in vibrating, do not move in the same direction at the same time, but always in opposite directions. They swing toward each other, then away from each other.

Experiment 14.—What is the effect of this movement

of the prongs of the fork on the air? A simple experiment will answer this question.

Place three lighted candles on the table at A, B, and C (Fig. 13). Hold the hands upright, with the space between the palms opposite A, while the backs of the hands face the candles B and C. Now move the hands near each other, then separate them, and make these motions steadily and not too quickly. You thus repeat the motions of the prongs of the fork. While vibrating the hands observe attentively the flames of the candles. When the hands are coming nearer each other, the air is

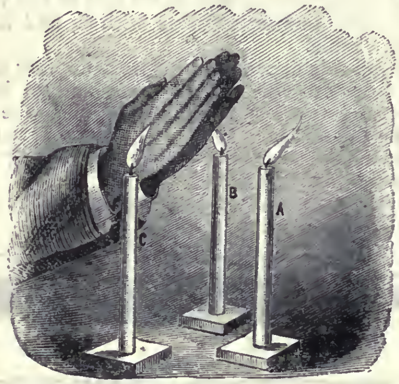

FIG. 13.

forced out from between them, and a puff of air is driven against the flame A, as is shown by its bending away from the hands. But, during the above movement, the backs of the hands have drawn the flame toward them, as shown in Fig. 13. When the hands are separating, the air rushes in between them, and the flame A is drawn toward the hands by this motion of the air, while at the same time the flames at B and C are driven away from the backs of the hands. From this experiment it is seen that the space between the prongs and the faces of the prongs

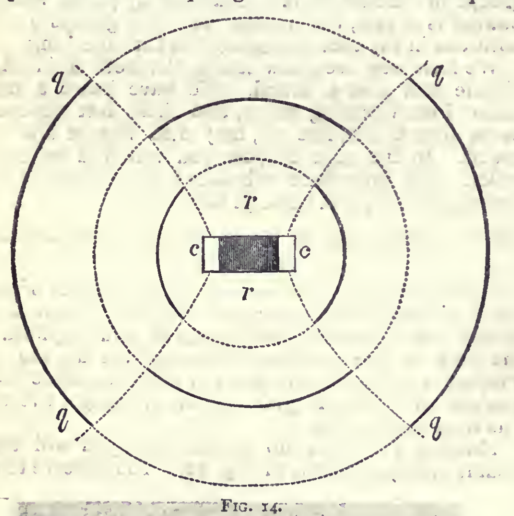

FIG. 14.

of a fork are, at the same instant, always acting oppositely on the air.

This will be made clearer by the study of the diagram, Fig. 14.

This figure supposes the student looking down on the tops of the prongs of the fork. Imagine the prongs swinging away from each other in their vibration. Then the action of the faces c and c on the air is to condense it, and this condensation tends to spread all around the fork. But, by the same movement, the space $r\,r$ between the prongs is enlarged, and hence a rarefaction is made there. This rarefaction also spreads all around the fork. But, as the condensations produced at c and c and the rarefaction at r and r spread with the same velocity, it follows that they must meet along the dotted lines q, q, q, q, drawn from the edges of the fork outwards. The black $\frac{1}{4}$-circle lines around the fork in Fig. 14 represent the middle of the condensed shells of air, while the dotted $\frac{1}{4}$-circle lines stand for the middle of the rarefied shells of air.

Now what must happen along these dotted lines, or, rather, surfaces? Evidently there is a struggle here between the condensations and the rarefactions. The former tend to make the molecules of air go nearer together, the latter try to separate them; but, as these actions are equal, and as the air is pulled in opposite directions at the same time, it remains at rest—does not vibrate. Therefore, along the surfaces q, q, q, q, there is silence. When the prongs vibrate toward each other they make the reverse actions on the air; that is, rarefactions are now sent out from c and c, while condensations are sent from r and r, but the same effect of silence along q, q, q, q is produced.

Experiment 15.—That this is so is readily proved by the following simple experiment:—Vibrate the fork and hold it upright near the ear. Now slowly turn it round. During one revolution of the fork on its foot you will perceive that the sound goes through four changes. Four times it was loud, and four times it was almost, if not quite gone. Twirl the fork before the ear of a companion; he will tell you when it makes the loudest sound and when it becomes silent. You will find that when it is loudest the faces c, c of the prongs, or the spaces r, r between them, are facing his ear; and when he tells you that there is silence you will find that the edges of the fork, that is, the planes q, q, q, q, are toward his ear.

(*To be continued.*)

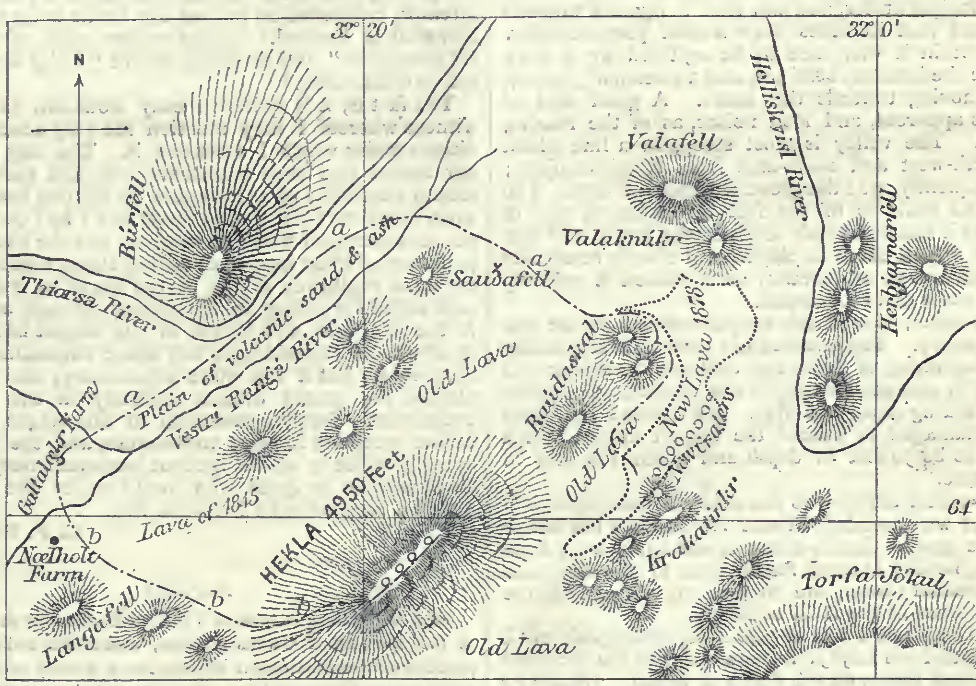
ON AN ASCENT OF MOUNT HEKLA, AND ON THE ERUPTION OF FEBRUARY 27, 1878

ON February 27 last severe earthquakes were felt throughout the south-west portion of Iceland, particularly in the districts of Land, Rangarollir, Hreppa, and Fljotschlith, which are situated immediately to the south and south-west of Mount Hekla. Between 8 and 9 P.M. an intense illumination of the sky, at first believed to be actual fire, was seen to the south-east. This was found to be due to the reflection by clouds of the light emitted by molten lava within a subsidiary crater, or *bocca del fuoco*, as the Italians would call it, of Hekla. On the following day dense columns of smoke ascended from the crater, and quantities of volcanic ashes fell in the districts of Hreppa and Biskupstundur. The light was seen at Reykjavik, nearly seventy miles distant, and there appeared to be two vents of fire.

One month after the eruption Prof. Tómas Hallgrimson visited the district and endeavoured to discover the exact position of the new crater. He found it in the Raúdaskal Valley, about four miles to the north-east of Hekla, and in connection with one of its outlying spurs. The chief crater was observed to be near the northern base of Krakatinkr, and a good deal of new lava was heaped around it. Herr Nielsens, a merchant of Eyrabakki, on the southern coast of Iceland, visited the scene of the eruption about the same time, and by ascending Krakatinkr he was able to look down into the new crater. He also determined its position, and traced the course of the new lava streams. The map which is here reproduced (for which I am indebted to Sjera Gudmundr Jonsson, the priest of Stóruvellir, a hamlet near to Hekla) is a copy of Nielsens' sketch made on the spot.

Upwards of a month ago (August 21) I visited the scene

of the eruption, in company with three friends. Two guides accompanied us, and we took a relay of ponies in case of accident or fatigue. We left the Galtalœkr farm (see the map, route *a a*) at 7.30 A.M., crossed a small streamlet, and soon came upon a growth of dwarf birch-trees from one to two feet in height. Here we put up a covey of very tame ptarmigan. On emerging from the underwood we entered a long level plain of volcanic sand and ash, extending between the river Thiorsa and the smaller stream called Vestri-Rángá. We cantered over the plain for about ten miles, turning aside for a moment to look at the falls of the Thiorsa, at the southern base of Búrfell. The substance of the plain is black volcanic sand and ash, with occasional white, grey, and red patches of pumice. At 9.15 A.M. we found ourselves near the termination of the Vestri-Rángá, and, bearing to the south-east, we forded the stream, and almost immediately afterwards came upon fields of volcanic ash and lava. The ground now became very rough, masses of lava were strewn in all directions, and there was of course no track. We passed several cones of ashes emitted by extinct craters, and presently saw in front of us Raúdaskal—the red mountain—a subsidiary cone probably thrown up in 1554. We wound along the Raudaskal valley, which is between six and seven miles in length and nearly two miles broad, passing by the base of several large cinder-cones. The new lava of 1878 was soon sighted, and we picked our way for about three miles between the edge of the field and the sloping sides of the cinder cones. By the time we had ridden some twenty-three miles from Galtalœkr we found ourselves at the edge of a field of old lava, contiguous to the lava of 1878, and in sight of the largest of the new craters. The summit of Hekla was on our right, about four miles distant, and Krakatinkr was nearly facing us to the south. Here we left the ponies, tied head and tail together, to prevent straying during our absence. The only possible way to get nearer to the new crater was to clamber over the old



Map of Mount Hekla showing position of the new craters. Route *a a*, from Galtalœkr to the new craters. Route *b b*, from Galtalœkr to the summi Hekla. The dotted line between Valaknukr and Krakatinkr shows the position and extent of the lava field of 1878.

Scale $\frac{1}{240,000}$. ¼ ½ 1 × 2 Miles Danish.

bed of lava, which, although very rough and jagged, was not difficult to cross, on account of its covering of moss. At the edge of this bed we came upon a small tract of old snow, covered with volcanic ash to the depth of about eight inches. Then we reached the new lava and saw the largest cone of the new craters immediately in front of us, and about half-a-mile distant. The new lava was more rough and cindery, at least at the surface, than any I have ever seen around Etna or Vesuvius. Its surface was extremely jagged, and it was broken into ridges, and crests, and sharp pinnacles, which yielded uncertain support to the foot or hand. Hence it was both difficult and dangerous to cross, and we could only climb over a few dozen yards of it. Standing upon its surface we could see the cone of the largest of the new craters emitting small quantities of vapour and incrusted with red and yellow substances. The lava field extended both to our right and left, and in some places it was giving off vapour. The edge of the field along which we travelled was about twenty feet in depth, but in some places it was piled to a much greater height. The lava was very close and compact some distance from the exterior; it was cracked and split in all directions. White incrustations of salt (*not* chloride of ammonium, which is common in some lavas) were often noticed at the points of fracture; also brilliant red and yellow incrustations, which are often mistaken for sulphur, but which in the case of this lava, at least, I have proved to be *sesquichloride of iron.* In some parts of the lava these incrustations covered many square yards, while fumes of hydrochloric acid were freely emitted in their vicinity. The sesquichloride when removed from the lava rapidly absorbed moisture from the air and formed an intensely acid solution. We left the neighbourhood of the new crater at 2.30 P.M., rested at 4 P.M. on the banks of the Vestri-Rángá, and reached Galtalœkr at 6.15 P.M., having left it eleven hours before, and travelled over nearly fifty miles of volcanic country.

Two short accounts of the eruption have been published in Icelandic, the one by Prof. Hallgrimson, the other by Herr Nielsens. These have been translated for me by Herr Matthias Jockumsson, of Reykjavik, to whom I beg to express my acknowledgments. According to Hallgrimson there are fourteen small craters situated in a line passing from west-south-west to east-north-east, which line, if prolonged, would pass through the centre of the craters on the summit of Hekla. The distance between the extreme craters of February 27 is about 6,000 feet. The lava flowed more than a mile to the south of the largest of the new craters, but the main stream flowed to the north and north-east, and nearly reached the Mountain Valaknúkr.

Nielsens approached the scene of the eruption, a month after its commencement, from the north-west, and passing between Valafell and Valaknukr, he went due south to Krakatinkr, along the eastern edge of the new lava. From the summit of Krakatinkr he looked down into the principal crater, and saw that it opened towards the east, and that its sides were almost perpendicular. The lava within it was seen to be agitated by a wavy motion like the billows of the sea, and a stream of glowing lava was moving towards the south. A good deal of vapour was apparent, and loud noises, as of the roaring of the sea. The valley is most steep, in a line which passes north-west and south-east from Raudfossafyall; here, consequently, was the greatest depth of lava. The stream varies from 10 to 100 feet in thickness, and in some places it has burrowed beneath the snow and ice. The lava is almost black in colour, and closely resembles the old Hekla lavas in texture; as it cooled it split up with great noise and commotion.

Nielsens again visited the neighbourhood of the new crater on June 9. The lava had not increased in quantity since the beginning of April, but columns of vapour still arose from it, and small quantities of ashes and of pumice had fallen during April and May. He crossed the warm lava and managed to ascend the largest crater, which was found to be 90 feet in depth and about 100 feet in circumference.

Two days after our visit to the scene of the eruption of February 27 we ascended Mount Hekla from the south-west. The general details of the ascent I now copy from my journal, hoping at some future time to produce them in a less desultory form, and to give an account of the analysis of some of the lavas of Hekla.

We left Galtalœkr Farm at 9.40 A.M., taking with us G. Zöega, a guide from Reykjavik, together with the occupant of the Nœfholt Farm, on the flanks of Hekla. (Route *b b* on the map). Having crossed the Vestri-Rángá, we proceeded nearly due south, passed the Nœfholt Farm, near which we came upon the lava of 1845; and then passed over some very rough lava-strewn ground covered with volcanic ash, which concealed holes into which the ponies sometimes stumbled and fell. The lava of 1845 is covered with the same moss which we noticed on the old lava near the crater of 1878, which causes it to look much older. When the ascent became greater, we left the ponies. Distance to foot of steep incline about seven miles from Galtalœkr. Followed the southern boundary of the lava-field of 1845, until we reached a steep incline which we ascended. Crossed a small portion of the old lava field, then a tract covered with volcanic ashes, and finally found ourselves at the bottom of a steep slope covered with snow, beneath which water was heard rushing downwards. The ascent of this slope without alpenstocks was not easy. Several other snow slopes were crossed, and we then found ourselves near the crater of 1845—the most westerly of the four craters on the summit of Hekla. Above this we saw a crater with a red smoking mound within it; then in succession the third and fourth craters, and beyond the most easterly crater a nearly level snow-covered waste full of lava blocks. From the most easterly extremity of this, which was reached at 2.30 P.M., we looked down upon the principal crater of 1878. The summit of Hekla is covered with much ash, sand, and red pumice, together with lavas of every degree of compactness, from the most vesicular up to obsidian. The descent over the snow-slopes was troublesome, on account of their steepness and the slipperiness of the snow, but we regained the spot at which we had left the ponies at 5 P.M.

Hekla was ascended for the first time in the year 1770. The difficulties of the ascent have been much exaggerated subsequently. Many travellers have made no attempt to scale the mountain. Even the "American in Iceland," who was in the neighbourhood of Hekla only three years ago, asserts that "the obstacles, real and imaginary, stated to be in the way, such as tortuous and difficult paths, swollen rivers, depth of snow, treacherous bogs, and the evident indisposition of the guides, perhaps from superstitious fears, to make the attempt, compelled us to turn our backs upon this snowy monarch of Iceland." Other writers speak of the "fearful precipices" and of places where "a slip would be to roll to destruction."

The fact is, it is quite an easy mountain to climb, in witness whereof I may mention the very abnormal conditions under which I ascended it. The day preceding our ascent had been extremely wet, and there was at least a possibility of a downpour on the day itself; moreover, there were streams to ford, and I had consequently put on waterproof wading stockings, and the usual accompaniment of thick iron-clad wading clogs, which, although the most cumbrous things in the world to walk in, are well suited for riding in the humid climate of Iceland. If the steepness and length of the ascent had required it, of course I should have left these encumbrances with the ponies, but it was quite unnecessary, and I accomplished the ascent without difficulty in this unwieldy equipment. Surely a mountain of this height was never before ascended in clogs and waders, and the fact of its being possible to do so without inconvenience, is a sufficient answer to those who would make the ascent of Hekla a dangerous and difficult feat.

G. F. RODWELL

NOTES

THE moderation in tone of Viscount Cardwell's short address at the opening of Owens College, makes his estimate of the position of that institution all the more worthy of acceptance. He is inclined to regard it as the most singular acquisition to the academical strength of the county since the middle ages; and we venture to think that one chief reason why it occupies so distinguished a position is the completeness, the all-roundness of the education which it furnishes. There, science and letters are on an equal footing, and it will only be when this is the case in all our educational institutions that the educational apparatus of the country will be thoroughly efficient. The fact that Owens College now administers funds exceeding 400,000*l*., all obtained from private sources, is one proof that it fills a great want. We have on previous occasions spoken of its claims to be erected into a university. The tone of Lord Carnarvon's address at Saltaire, was in effect similar to that of Lord Cardwell; education is incomplete unless all our faculties have equally fair play.

ACCORDING to the Naples correspondent of the *Times*, Prof. Palmieri does not think there is any likelihood of a violent eruption of Vesuvius. The mountain has been in an eruptive state for two years; the cup is full, and must run over, but will probably do so quietly. The state of Vesuvius gives some interest to the project of the construction of a railway intended to conduct travellers from Naples to the margin of the crater. The scheme, proposed by a Neapolitan banker, has just been adopted.

According to the *Italie*, the waggons will be dragged by a rope. The length of the way will be only 840 metres, and the altitude reached 490 metres above the level of the sea. Each waggon will have only four seats, and four waggons, carrying sixteen passengers, will go up at the same time that four others loaded with sixteen persons will come down. Each waggon will be supplied with a patent brake for stopping instantly if the rope breaks.

THE death is announced, at Milan, of Signor Giulio Curioni, a distinguished chemist, metallurgist, and geologist, in his 82nd year.

MR. EDISON, the *Polytechnic Review* states, has made some experiments with a view to accomplishing the reading of the phonograph record by sight; but although a fundamental form exists for each articulated sound, he finds it very difficult to free the record from what might be called accidental influences; for so sensitive are these markings that the same sound uttered by different persons, or the manner in which it is spoken, the distance of the mouth from the instrument, the force with which it is spoken, or the speed with which the barrel is rotated, gives a different form of indentation. Vowel sounds appear to be but little affected by these variations as compared with consonants.

ABOUT 14,000 telephones, we learn from the *Polytechnic Review*, had been introduced into the United States up to the close of the year 1877, and the manufacturers are receiving orders at the rate of about a thousand a month.

WE learn from the Report of the British Association Committee on Erratic Blocks, presented by Rev. H. W. Crosskey, that the Committee were supplied with notes on boulders near Kendal by Mr. J. R. Dakyng. The most remarkable are those of the granite of Wastdale Crag, near Shap Wells, the distribution of which seems to show that they must have travelled over the high ground south of the granitic area, and not have followed the course of the present drainage. The general due south course of the boulders is shown by their distribution south of Kendal. They have been traced as far south as Milnthrops and occupy a narrow band of country whose long axis point, directly to the granite of Shap Fells. The most westerly are some near Hincaster, and a line drawn from the most westerly outcrop of granite on Shap Fells to these boulders bears south by west. The most easterly in this neighbourhood is in a field near Windy Hill, about two miles south-east of Kendal railway station, but one has been found high up on the side of Grayrigg Fell. Boulders of the dark compact altered rock that surrounds the granitic area are generally found along with the granite boulders. When the localities where granite boulders occur are marked on a map, the steady lineal north and south direction of their course is very striking. Boulders of the ordinary volcanic rocks of the Lake Mountains indicate other directions for the ice-flows. One of these may be seen two and a half miles out of Kendal, and east of the line of granite boulders. As the granitic area of Shap Fells is at the extreme east end of the volcanic rocks, this boulder must have crossed the line of flow along which the granite boulders travelled. Some new facts were reported by Mr. MacIntosh relative to the derivation of boulders already recorded, the existence of several large boulders previously unnoted, and by the extent to which Ireland has sent erratics into England. The report further contained descriptions of the position and character of many large boulders and groups of boulders in Leicestershire and Staffordshire.

IT is announced that a second session of the International Congress of Ethnographical Science which met under the patronage of the French government in July last at the Palace of the Trocadéro, will be held on October 10 next at the Palace of the Tuileries. This session is to be held in order that those who were unable to attend in Paris in July last may now have an opportunity of being present at the congress. In the course of a few days a programme will be published of the questions to which special attention is to be called. The committee of the Ethnographical Society of Paris which is organising the congress are especially desirous that England should be well represented on the occasion.

IN a recent issue of the *Indian Tea Gazette* we find some interesting notes of an attempted journey towards China, overland from Assam, extracted from the journal of Mr. C. H. Lepper, who, attracted to the subject, no doubt, by his previous residence in China and Japan, has always kept in view, since his arrival in Assam, the idea of taking advantage of the magnificent Brahmapootra as a road to within about 200 miles of the frontier of the province of Yünnan. His residence being only sixteen miles from Suddya, the furthest outpost on the north-east of India, he has had constant opportunities of making inquiries from the intervening peoples in regard to the distance, state of the tribes, &c., between our frontier and China. These proved so satisfactory in their results that early in 1876 he was induced to make an attempt to advance as far as possible in the direction of China with the object of obtaining more precise and practical information. Before the party left Suddya, the *mehla* or fair for the hill tribes had just been held, at which Chow Mang Ti, a chief of the Kamptis, acts as interpreter for that tribe and the Singfoos, who assemble there in considerable numbers. His brother, Chow Kun, accompanied Mr. Lepper as head of the Kampti guides, and in the course of conversation Chow Mang Ti stated that there would be no difficulty in getting through the intervening country to the Chinese border. Passing up the Brahmapootra, the party entered the Tenga Pani River through the Noa Dehing. They found the first three or four miles had a sandy bottom, with great quantities of the silkworm-feeding *Soom* tree on the banks, on which the forest soon became dense and the scenery beautiful. Near the first rapid is a pretty islet, named Shikar Mazeli, which, when seen from a point a little further up the stream, Mr. Lepper describes as "perfectly enchanting." After passing the village of Juna or Chuna, Mr. Lepper says "we soon came to a bend, having a very high forest facing us on a hill, containing banyan, valuable saul trees in great quantities, also uriam and soom trees; we noticed, too, the Bazal bamboo appeared again, bamboos up to within a short distance of this hill not having been seen on the river. The 'surat,' a horrid leaf, which, if touched, causes intense pain for days, is prevalent, also a kind of wild chestnut. Plantains, *toku pat*, *tora pat*, tree ferns, orchids, and other parasites, all help together with graceful patches of cane to make the picture perfect." Owing to numerous rapids progress was slow, and it was late on the fourth day when the party reached Shangkam, where they were kindly received by the Kamptis. After they had waited some time, Chow Mang Ti arrived from Suddya, and to their great disappointment assured them that it would be useless to attempt to proceed towards China at that time of the year, as the rainy season had set in. He, however, gave some information on points connected with the route to China. "It takes eight days," he said, "to reach Hobong, between which place and this you could get no supplies, and it would take you about sixteen days to get there. Hobong is a large town. Then it takes us eight days more to reach the Irrawaddy River, and would take you at least sixteen or eighteen days. It is between Hobong and the Irrawaddy that the ascent I told you of has to be made. A little past Hobong are the two hills of almost pure silver; . . . there is a great quantity of gold there too, which gives that little colony of ours the name of Kamp Thi, meaning gold country, by which name you call all of us, who are really Shans from Shan, a country lying nearer China,

having a strip of Singfoo country lying between us and our colony of Kamp Thi. The Singfoos, again, lie between our Shan country and China. This Hobong route is better than the Hukong route, which leads to Burmah, as the Noa Dehing is not navigable now." As it was impossible to prosecute his projected journey without Chow Mang Ti's assistance, Mr. Lepper deemed it prudent to acknowledge the weight of the arguments which he advanced against making the attempt at that season, the more so as he was aware that the Government of India objected to Europeans crossing into the territories of the hill-tribes, and he had only obtained permission to cross the "inner line" on the ground that he desired to visit the Brahma Khund or Sacred Pool of Brahma. He accordingly descended the Tenga Pani River, and then proceeding up the Brahmapootra, visited the Sacred Pool, a spot which few living Europeans have ever reached.

FROM time to time we have given various examples of the progressive tendencies of the Japanese in many directions, and we are glad to be able to supplement them with the information that they are turning their attention to the dredging of their harbours. We learn from a Japanese contemporary that the ports of Niigata, Ishinomaki, and others are to be dredged and improved in such a way as to be most convenient for shipping. The Bay of Hachiro, in the province of Ugo, is to be dredged, at the estimated cost of a million *yen*. Mr. John Perry, engineer in the employ of the Public Works Department, and a number of students of the Survey Department were sent there in April in order to survey the bay, and their inspection will probably be completed in October. This work is the more important as there is no safe shelter for vessels in stormy weather between Hakodate and Tsuruga.

MR. EDWARD STANFORD has the following books and maps preparing for publication:—A fifth edition, greatly enlarged, of "The Physical Geology and Geography of Great Britain," by Alexander C. Ramsay, LL.D., F.R.S., Director-General of the Geological Surveys of the United Kingdom, with Geological Map printed in Colours, and numerous Illustrations; "Notes of a Tour in America from August 7 to November 17, 1877," by H. Hussey Vivian, M.P., F.G.S., with Map; "The Fairy-land of Science: Chapters for Children," by Arabella B. Buckley, Illustrated; "Karamania; or, Life in Asiatic Turkey: a Journal of Travel in Cilicia (Pedias and Trachæa), Isauria, and Parts of Lycaonia and Cappadocia," by the Rev. E. J. Davis, M.A., English Episcopal Chaplain, Alexandria, Illustrated; "Manual of Physical, Historical, and Political Geography for Schools," by Keith Johnston, F.R.G.S., with numerous Maps and Illustrations; "Stanford's Compendium of Geography and Travel—Europe," Edited and Extended by Prof. A. Ramsay, F.R.S.; "Australasia," Edited and Extended by A. R. Wallace, F.R.G.S.; also in preparation, uniform with the last, "Asia," Edited and Extended by Col. Henry Yule, C.B., F.R.G.S., "North America," Edited and Extended by Prof. F. V. Hayden, of the United States Geological Survey; "Elementary Physics for Middle-Class Schools, with Experiments and Illustrations, to which are added Examination Questions on each Section," by John A. Bower, Science Master, Middle Class School, Cowper Street, London. Among Maps Mr. Stanford will publish an "Orographical Map of Asia," for Use in Schools and Colleges," Edited by Prof. Alexander C. Ramsay, F.R.S.; "Library Map of Japan," Compiled by E. Knipping; size, 4 feet 6 inches by 5 feet 6 inches; scale 17 miles to an inch; this is an entirely new and original map, compiled from the various large divisional Maps prepared by the Japanese, and corrected and extended from journeys made for the purpose by the author; Supplementary maps show the railways, chief roads, telegraphs, and lighthouses, and the new administrative divisions introduced in 1876; "Library Map of Africa," new edition, with the Results of all Recent Explorations carefully laid down; "School Map of Africa;" new edition; size, 50 inches by 58; scale 118 miles to an inch; "Library Map of South America;" new edition; "Library Map of Australia," in nine sheets; constructed from the most recent Official Documents furnished by the Surveyors-General, showing the Details of Recent Explorations, and including a supplementary Map of Tasmania; on the same scale; "General Map of Australia," with all the recent explorations, the roads, railways; and a "School Map of New Zealand."

MESSRS. E. AND F. N. SPON will publish during the forthcoming season:—"The Chemist's Pocket-Book," by Thos. Bayley; "The Power and Speed of Steam Vessels Calculated by Rules adapted for Vessels of all Types," by W. Bury, Mem. Inst. M.E.; "A Treatise on Bridge and Roof Construction," by Karl von Ritter, translated from the German by Lieut. Sankey, R.E.; "Applied Mechanics," by Prof. Calcott Reilly, M. Inst. C.E.; "Graphic Arithmetic," by G. S. Clarke, Instructor in Geometrical Drawing, Royal Indian Engineering College, Cooper's Hill; and a "Supplement to Spon's Dictionary of Engineering." M. Ch. du Moncel has published in the "Bibliothèque des Merveilles" a volume on "The Telephone, Microphone, and Phonograph," in which he describes in a popular form all the discoveries which for the last two years have astonished the world.

MESSRS. WILLIAMS AND NORGATE have sent us "Karl Ernst von Baer; eine biographische Skizze," by Dr. Ludwig Stieda, and "Karl Freidrich Gauss, Zwölf Kapitel aus seinem Leben," by Ludwig Hänselmann. Messrs. Longmans and Co. have published a fourth edition of Prof. Fleeming Jenkin's text-book on "Electricity and Magnetism."

FROM America we have received the "Bibliography of North American Palæontology," by Dr. White and Prof. Alleyne Nicholson (Washington Government Printing Office), and "Annals of the Astronomical Observatory of Harvard College," vol. iv. part 2 (Cambridge, U.S.: Wilson and Son). From Australia we have Decade 5 of the "Prodromus of the Palæontology of Victoria," by Mr. F. McCoy, of the Victoria Geological Survey; "Meteorological Observations made at Adelaide Observatory during 1878," by Mr. Charles Todd; "Mineral Statistics of Victoria for 1877," and "Report of the Mining Surveyors for Victoria for Quarter ended March 31, 1878."

THE Chilian government has now established a meteorological service in all the ports that are connected by telegraph, and the daily observations are published in the government gazette at Santiago.

AN earthquake was felt at Pic-du-Midi Observatory on Wednesday, September 25, at 8h. 53m. in the morning. The snow was falling heavily. Heavy falls of snow have also been recorded in the Oberland, and communications with St. Gothard have been interrupted. Shortly after midnight on Friday the shock of an earthquake was felt at Osterath, in Germany.

FROM the 16th to the 18th of August the city of Cartago in Costa Rica, in Central America, was visited by five distinct shocks of earthquake. No particular damage was caused. What is to be noticed is the meteorological result: that the weather was changed, being attended by heavy showers that flooded the rivers. In all earthquake countries it is believed the weather is affected by such phenomena, and it is desirable that observations should be recorded, showing the influence of earthquakes on weather. It has been alleged that the Comrie earthquakes in Perthshire came on after rains and floods of the river.

PROF. KARL ARENDTS, of Munich, has been nominated corresponding member of the Lisbon Geographical Society, in acknowledgment of his merits in geography. Prof. Arendts is the editor of a new geographical serial, entitled "Deutsche Rundschau für Geographie und Statistik," published in monthly parts by Hartleben, of Vienna.

"VIH CHE SIN LOO" (magazine for the propagation of knowledge) is the title of a new monthly publication in the Chinese language, edited by Dr. Edkins, of Pekin.

SECCHI'S "Meteorologica Romana" has just been published by the Italian government. The last revision of proofs was made by Secchi's friend, Sig. Ferrari, death having prevented the great astronomer himself from finishing this last part of his work on the meteorology and climatology of the Eternal City.

THE twenty-third meeting of German and Austrian apiculturists took place at Greifswald on September 11-13, and was attended by over 700 persons.

THE International Agreement regarding the steps to be taken for protecting the wine-growing districts against phylloxera, was signed at Berne on September 17.

RECENT borings made in different parts of North Germany have proved beyond denial that the assertion made by several eminent geologists, that a mighty deposit of salt stretches from the Lüneburger Heide to the coast of the Baltic, is perfectly correct. The deposit begins near Lüneburg, passes underneath the Elbe, and extends right across the Grand Duchy of Mecklenburg. Another branch goes in the direction of the Duchy of Holstein, *viâ* Legeberg to Elmshorn and Heide. Borings made at Lübtheen, near Hagenow, by order of the Mecklenburg government, have now reached a depth of 456 metres, and the thickness of the deposit of salt now reaches 130 metres; the basis, however, is not yet reached.

THE *Palæontologist* is the name of a new journal of small size published in Cincinnati, devoted to the subject indicated by its title. It will be published from time to time as matter accumulates.

AMONG the many rare shells lately belonging to Dr. Marie, of New Caledonia, is a new Murex, which will be described by Mr. Bryce Wright in the next number of the *Proceedings* of the Malacological Society of Belgium, under the name of *Murex huttonæ*.

STUDENTS of physics will be glad to learn that Gauthier-Villars has just issued a complete collection of the papers of the lamented Léon Foucault. They are preceded by a notice from the pen of M. Lissajous.

RECENT numbers of *Globus* contains an account, by Dr. Schröder, of his second visit to Cyprus in 1873.

HERR GERHARD ROHLFS will start for a new exploring tour to Africa in the first week of October. He will be absent some eighteen months, and he begins his journey *viâ* Tripolis and Wadai.

IN the Barmsee, a small lake situated in the Bavarian mountains, near the villages of Mittenwald and Krün, not far from the Austrian frontier, numerous piles, dating from pre-historic lake-dwellings, have just been discovered by Herr Zapf. The massive piles are standing upright in the lake; some of them still show incisions and spikes on their surface, indicating the spots where they were united, or where planks rested upon them. They stand in rows parallel to the southern shore of the lake. Other rows run in a northerly direction, but in the latter the piles are smaller and stand close side by side, forming a sort of palisade. None of the piles now reach the surface of the water. The total length of these pile-dwellings is about 200 metres.

THE *Precurseur d'Anvers* publishes a letter from Zanzibar stating that the Belgian expedition had reached a place situated some distance in the interior. Owing to a misunderstanding, they were compelled to engage in conflict with the natives, and eventually had to seek refuge in flight. It is not yet known whether they succeeded in escaping or were murdered.

AN American Microscopical Congress met at Indianapolis on August 14–17, under the presidency of Dr. R. H. Ward. Nineteen papers in various departments of microscopical research were read. The congress resolved itself into a permanent organisation under the name of the American Society of Microscopists.

THE Christchurch (N.Z.) *Press* contains a description of a very complete physical, chemical, and metallurgical laboratory which has been established in connection with Canterbury College. It is well provided with the best apparatus, and is well fitted both for original research and for student work.

WE have received a neat and attractive little "Guide to the Upper Engadine," by Dr. J. Pernesch, published by Orell Füssli and Co., of Zurich. It contains useful and well-arranged information, with a small map and twenty-one well-executed illustrations.

WE have received the July number of the *Anales* of the Argentine Scientific Society, which, besides an account of the proceedings of the society, contains a narrative of journeys in Patagonia, by Ramon Lista, papers on the composition of the water of the Uruguay, by Mr. J. J. Kyle, on the Hemiptera Argentina, by Carlos Bery, and on the flora of Paraguay, by Domingo Parodi.

WE are asked to publish the following statement:—During the recent opening of the Grosvenor Gallery on Sunday, nearly 6,000 persons availed themselves of the privilege of visiting the exhibition. This success has encouraged the committee of the Sunday Society to arrange for the exhibition of a series of water colour drawings of Swiss life and scenery, sketched in Switzerland by Mr. William L. Thomas. The exhibition will be opened on the first three Sundays in October, from 2 to 5 P.M., at 33, New Bridge Street, Blackfriars, E.C. (the late offices of the London School Board), and the public will have free access to it by means of tickets, which will only be issued to those applying by letter, and sending stamped and addressed envelope to the Honorary Secretary, 19, Charing Cross, S.W. The Committee of the Sunday Society intend to continue these Sunday Art Exhibitions from time to time, until the Society's object is accomplished, and the public Museums, Art Galleries, and Libraries, are all opened on the people's weekly leisure day. The Society will be glad to receive pecuniary and other assistance to enable the Committee effectively to carry on these exhibitions.

THE separation of the Central Bureau of Meteorology of the French Government is an accomplished fact, and the officers will be located in an hotel in the Rue de Grenelle, St. Germain, where no readings can be taken, the inspection of the sky being as difficult as from the British Office in Victoria Street. These peculiarities have raised much sharp criticism, and it is not certain that this solution will be accepted by the French Legislative Assembly. It has been suggested that the Bureau should be located at the Trocadéro, or on the top of the Arc de Triomphe, where there are magnificent rooms in which offices could be established.

THE additions to the Zoological Society's Gardens during the past week include a Bonnet Monkey (*Macacus radiatus*) from India, presented by Mr. Frederick Carter; two White-crested Touracous (*Corythaix albocristata*) from South Africa, presented by Mr. W. Wormald; a Green Turtle (*Chelone viridis*) from the Island of Ascension, presented by Capt. J. Smith; a Tabuan

Parrakeet (*Pyrrhulopsis tabuan*), a Masked Parrakeet (*Pyrrhulopsis personata*) from the Fiji Islands, purchased; a Chestnut-backed Weaver-bird (*Hyphantornis castaneo-fusca*), four Rufous-necked Weaver-birds (*Hyphantornis textor*), two Grenadier Weaver-birds (*Euplectes oryx*), a Barbary Turtledove (*Turtur risorius*), a Vinaceous Turtledove (*Turtur vinaceus*) from West Africa, a Turquosine Parrakeet (*Euphema pulchella*) from New South Wales, two Undulated Grass Parrakeets (*Melopsittacus undulata*), seven Crested Ground Parrakeets (*Calopsitta novæ-hollandiæ*) from Australia, deposited; eight Mocassin Snakes (*Tropidonotus fasciatus*), born in the Gardens.

THE FIGURE AND SIZE OF THE EARTH[1]

III.

DURING the years 1816-52 a Russo-Scandinavian degree-measurement was carried out by Struve and Gen. Tenner, of unusual length and wonderful accuracy. It extended from Hammerfest in the north (70° 40′) to Ismail in the south (45° 20′), a length of 25° 20′. From this it followed that for latitude 56° 3′ 56″, the degree length is 57,137 toises, and in this was included a Swedish degree-measurement which gave 57,209 toises as the length of a degree in lat. 66° 20′ 12″. At this time extensions of earlier operations were undertaken in other countries; as in England with the result of $\frac{1}{280}$ for the earth's oblateness. Everest extended Lambton's East Indian degree-measurement, which at present has a length of over twenty-one degrees. Also a longitude measurement begun at an earlier period in Central Europe was recommenced and reaches now from Brest, Paris, Strassburg, Munich, to Vienna. With the assistance of the new data the amount of the earth's oblateness was again investigated, and now that there was no doubt of the accuracy of the measurements, it was shown distinctly that the earth was not an entirely regular elliptical spheroid, that the flattening did not pass regularly over the earth's surface. The theory was next propounded that the earth was an ellipsoid of three axes, but the proposition was not fully supported by the measurements.[2] A newly elaborated mathematical method, by which from the existing measurements, the figure of the earth could be obtained, and by which the remaining errors could be reduced to a minimum, was now applied by the great Bessel to the data before him, and according to these principles and on the basis of the best measurements, he obtained dimensions of the earth which still form the ground of all astronomical and geodetical calculations, and which are as follows:—He found for the equatorial radius of the earth 327207714 toises = 6377400 metres; for the polar radius 326113933 toises = 6356080 metres; and for the length of the earth's quadrant 10000855765 metres; while he gave the earth's oblateness as $\frac{1}{298 \cdot 153}$. He also deduced formulæ giving the length of a degree or of a parallel of latitude for any part of the earth; these formulæ will be found in most geodetic handbooks. New values for the dimensions of the earth were, ten years ago, deduced by Leverrier with the assistance of other measurements, but they differ very little from those of Bessel, and in almost all scientific works Bessel's constants are adopted. Thus, about the middle of the present century the solution of the original problem has been attained. And yet since that time there has unmistakably been an altogether unusual progress in all departments concerned in the solution of the problem. First of all, mechanical precision has in the last decades attained such perfection, that now astronomical observations, and especially the geographical determination of places, can be made with considerably greater accuracy than was possible a few decades ago. Moreover, these improvements have been accompanied with extraordinarily suitable new methods. The telegraphic determination of longitude, a method for the determination of the lengths of parallels, has above all, especially in the last ten years, attained such perfection, theoretically and practically, that the measurements carried out on this method are most accurate, and we may justly expect in the future most brilliant results from it. Altogether the problem is near a more substantial solution now than it ever was before, as there are so many well-equipped observatories at work, bound together by a network of the most accurate determination of longitude and latitude, extended over the surface of the earth, and the completion of which is yet going on. Of the greatest importance also in this connection is the more recent theory of measurement, according to which the points to be connected need not lie in one and the same meridian or parallel, but, on the contrary, are connected by an arc of a great circle lying in any direction—the geodetic line.

Thus have we seen how from the remotest times, among all the nations of the earth not only has the wish to obtain a knowledge of the form and size of our dwelling-place prevailed, but also the most earnest activity in attaining this knowledge of nature; how this has in an increasing degree gone hand in hand with the progress of the mathematical and physical sciences, having at last reached a worthy solution in our time; and we have the best reasons for believing that, closely following the progress of the sciences, our knowledge in this connection will soon reach the highest degree of certainty.

[1] Continued from p. 580.

[2] This is scarcely correct: the figure of three unequal axes agrees better with the observations than does the spheroid of revolution. But there is a necessity for this, and the ellipsoidal figure cannot be regarded as established.

Remarks on Karl Maria Friederici's Paper, by Col. Clarke, R.E.

One feature of modern geodesy that has been left unnoticed by the writer of the foregoing paper is the application of the theory of probabilities, under the form of the "method of least squares," to the reduction of the observations. In any network of triangulation if it were required to obtain the distance apart of two of the extreme points, we should obtain varying results according to the set of triangles used in the calculation, and the question arises, What is the degree of credibility to be given to each result, or what the "probable error" of each? This implies, of course, that there is a superfluity of observations, that is, more than are absolutely necessary to fix all the points. If there were no superfluous observations there could be but one result obtained—an advantage in one respect (in saving calculation)—but then we should be wholly at sea as to the degree of trust to be placed in this one result. The theory of probabilities teaches us how to treat superfluous observations, and practically it leads to the calculation of a system of corrections to all the observations in order to bring them into harmony. Now there could be found an infinite variety of systems of corrections that would harmonise the observations, but the particular system we are led to by the method of least squares has this feature, that the sum of the squares of the corrections is an absolute minimum. In plain words, the triangulation is harmonised with the least possible alteration of the original observations as a whole.

These calculations, however, involve an enormous amount of labour, and one is compelled sometimes to relax the rigour of the theory, and accept some slight modifications. For example, in the triangulation of Great Britain and Ireland this method required the solution of an equation of 920 unknown quantities; this hopeless task was evaded by breaking up the triangulation into some fifteen or more parts.

The principal triangulation of India—unlike that which uniformly covers the face of this country—consists of chains of triangles running in a meridian direction crossed by several other chains perpendicular to them; as the longitudinal series from Kurrachee to Calcutta, and that from Bombay to Vizagapatam, the north-east longitudinal series, and others. The reduction of these chains of triangles by the method of least squares is a vast labour not yet completed.

The enormous mass of the Himalayan Mountains causes, or rather might theoretically be supposed to cause, an immense disturbance of the direction of gravity at the stations of the Indian arc amounting at the northern stations to 30″, with smaller amounts as the distances of stations southwards increases. Now it is very singular that, except at the very foot of the mountains, these discrepancies do not actually appear (to anything like that amount) in the arc itself or when it is used in the problem of the figure of the earth. This very remarkable circumstance has led to the hypothesis that the attraction of the superincumbent visible mass must be compensated for by a diminution of density in the strata underlying the mountains. Pendulum observations made for the purpose of elucidating this point have shown conclusively that the density of these underlying strata *is* actually less there than elsewhere. A compensation therefore takes place—but in a general way only; it cannot be shown that it is a mathematically exact compensation, consequently there is some residual doubt as to what really are the deflections of the vertical at the astronomical stations of the Indian arc.

We may supplement Karl Maria Friederici's account of how to calculate a meridian arc by a description of the method fol-

lowed in calculating a portion of the English arc where proceeding from the Yorkshire coast between Redcar and Whitby (the survey station is Easington) it crosses the sea in a line to Saxaford in Shetland. At Easington astronomical observations gave the azimuth of Cheviot as $38° 48' 58''\cdot68$. This determines the meridian; and the triangulation gives the relative distances and azimuths at the following succession of stations (selected for this calculation):—Cheviot; Mount Battock, on the Grampians between Aberdeen and Balmoral; Scarabin in Caithness, Fitty Hill in the Orkneys; Foula, a precipitous island between Orkney and Shetland; and Yell, a station in Shetland (not quite so far north as Saxaford (see Fig. 3).

On the meridian line defined above, take a point, A, whose distance from Easington is equal to the side "Easington to Cheviot." Join A with Cheviot and Mount Battock, and it is evident that we can determine the distance A to Mount Battock and the angle at A between Mount Battock and the north meridian. Next take the point D at a distance from A equal to the side "A to Mount Battock." Join D with Mount Battock and Scarabin, then we can determine the side "D to Scarabin" and its inclination to the meridian at D. Next take a point G (still in the same meridian) at a distance from D equal to the side "D to Scarabin," and join G with Scarabin, Fitty Hill, and Foula. Next take H at a distance from G equal to the side "G to Foula," and join H with Foula, Yell, and Saxaford. From Saxaford drop a perpendicular on the meridian meeting it in S; then we have the distance Easington to S, and the length of this perpendicular, which is about 200 feet. In order to verify this result a different set of stations were chosen for a second calculation conducted in a similar manner; the distance Easington to S by the first calculation was 2288427·29 feet; by the second it was 2288427·38 feet.

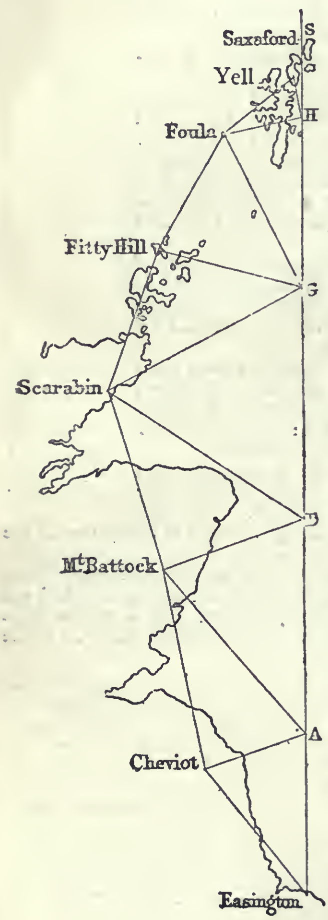


Fig. 3.

The volume of the Ordnance Survey entitled "Account of the Principal Triangulation of Great Britain and Ireland," by Capt. A. R. Clarke, R.E., contains (pp. 733–778) an elaborate calculation of the figure of the earth based upon the English and French arcs of eleven and twelve degrees respectively, the Russian and Indian of twenty-five degrees and twenty-one respectively, the first Indian arc, the Danish and the Prussian arcs of about a degree and a half each, the Peruvian arc of three degrees, and the Hanoverian arc of two degrees—a total length of eighty degrees within a few minutes. The figure is first investigated without restricting it to the elliptic form, but assuming that the radius of curvature of the meridian is expressed by the formula $\rho = A + 2B\cos 2\phi + 2C\cos 4\phi$ (the ellipse is a particular case of this curve, *i.e.*, if $5B^2 - 6AC = 0$). The resulting semi-axes are $a = 20927197$ ft., $b = 20855493$ ft., $a : b = 291\cdot9 : 290\cdot9$, and the meridian curve is more protuberant than an ellipse of the same axes by the quantity $\delta r = (177\cdot5 \pm 70\cdot9)\sin^2 2\phi$. But when the curve is restricted to the form of an ellipse the semi-axes are found to be 20926348 and 20855233 with the ratio of 294·26 : 293·26. The probable errors of the semi-axes so determined are ± 186 and ± 239 respectively.

Subsequently to the publication of the volume containing these investigations, an extensive series of comparisons of standards—the geodetic standards—of length of the various countries in which meridian arcs have been measured, was made at the Ordnance Survey Office, Southampton. In order that these most important comparisons might be made with the utmost attainable accuracy, a building was erected especially for this purpose. The comparison-room—itself double-walled—is surrounded and wholly inclosed within an outer building, and it is partly sunk below the level of the ground. The diurnal change of temperature is not perceptible in this room, consequently comparisons are made under extremely favourable circumstances. As a rule, each pair of standards was compared in summer at about the temperatures of 62°, and in winter at about 32° or 42°, but always at the natural temperature of the room, artificial temperatures being wholly excluded. To give an idea of the precision attained in these comparisons, the probable error of the length of the Ordnance Standard ten-feet bar in terms of the national yard is four ten-millionths of a yard; that of the Indian steel standard (a ten-feet bar) is less than three ten-millionths of a yard; that of the Russian standard, a bar of more than twelve feet long (two toises) is six ten-millionths. The importance of these results, connecting the largest arcs, upon which the figure of the earth must depend, can hardly be overestimated. The length of the "Toise of Peru" obtained through three entirely independent sources, viz., the Russian, the Prussian, and the Belgian toises, is 6·39453348 feet, from which the greatest divergence of the three separate results is only half a millionth of a toise; this corresponds to ten feet in the earth's radius. The length of the "metre" deduced from the above by means of its defining ratio (443296 : 864000) is 3·28086933 feet.

One of the most difficult of the determinations of length made in connection with this series was the measuring the distance between the knife edges of Kater's Reversible Pendulum. In this operation the flexibility of the bar was in the preliminary comparisons a source of much error. This, however, with some other troublesome matters, was successfully overcome, and the length was determined with a probable error of less than one five-millionth part of the length. The length of the pendulum was obtained by comparing it with the metre, and the details of the measurements will be published in the "Account of Pendulum Observations in India," by Col. Walker, R.E., F.R.S., Superintendent of the Great Trigonometrical Survey and Surveyor-General of India.

These results of the comparisons of standards of the different countries concerned, modify the numbers given above for the semi-axes of the earth. After making the necessary corrections, the semi-axes of the elliptic meridian are 20926062 feet and 20855121 feet, or 6378206·4 metres and 6356583·8 metres. The ratio of the axes 293·98 : 294·98. See the Ordnance Survey volume, entitled "Comparisons of Standards of Length," page 287. In the same volume will be found an investigation of the figure of the earth, supposing it to be an ellipsoid of three unequal axes.

But these results are now again superseded by a more recent determination published in the *Philosophical Magazine* for August. It appears that during the last few years the Surveyor-General of India, Col. Walker, C.B., F.R.S., Royal Engineers, has been not only measuring new arcs in India, both of latitude and of longitude, but has revised the southern portion of the Indian arc as measured originally by Col. Lambton. On this chain of triangles considerable doubt rested as to what was the unit of length used in the measure; a complete remeasurement according to modern methods has set this question at rest. A complete meridian chain of triangles has been carried from Mangalore on the west coast in latitude 12° 52′ and longitude 75° E., to a point in latitude 32°; thus the whole Indian arc is now 24° in length. Eleven differences of longitude have been determined by electro-telegraphy between the stations Mangalore, Bombay, Vizagapatam, Madras, Bangalore, Hydrabad, and Bellary; it is almost unnecessary to add that in these operations no refinements of modern science have been overlooked. As the difference of longitudes of Bombay and Vizagapatam is 10° 28′ and the geodetic connections of the above seven stations is completed (liable, however, to some small future corrections resulting from the least square calculations) there is thus presented a large addition to the data of the problem of the figure of the earth. Taking the English and French conjoined arc of 22° with fifteen astronomical stations; the Russian arc of 25° with its thirteen stations; the Indian meridian arc of 24° with

fourteen stations (this is not a fourth part of the number available), and the Indian longitude stations specified above, fifty-six equations treated by least squares give the following elements of the earth's figure :—

Polar semi-axis ... ... $c = 20854895$ standard feet.
Equatorial semi-axis ... $a = 20926202$ „ „

$$c : a = 292\cdot465 : 293\cdot465.$$

But the evidence of the Indian longitude observations goes to show that the curvature of the surface of India in a direction perpendicular to the meridian is considerably less than that belonging to the spheroid just specified. Possibly this apparent result may be owing to the existence of attractions of the plumb-line seawards at the coast stations. At any rate it suggests the re-investigation of the ellipsoidal form of the earth : and the result of a formidable calculation is that the ellipsoid best representing all the observations has the following semi-axes :—

$a = 20926629$ $b = 20925105$ $c = 20854477$,

and the ellipticities of the two principal meridians

$$\frac{1}{289\cdot5} \text{ and } \frac{1}{295\cdot8}.$$

The longitude of the greater axis of the equator is 8° 15′ W. of Greenwich—a meridian passing through Ireland and Portugal, and cutting off a portion of the north-west corner of Africa ; in the opposite hemisphere this meridian cuts off the north-eastern corner of Asia and passes through the southern island of New Zealand. The meridian containing the smaller diameter of the equator passes through Ceylon on the one side of the earth and bisects North America on the other. Thus the division of the earth by the meridian plane of the greater axis of the equator corresponds very nearly with the ordinary two-circle representation of the earth, the one showing the Eastern hemisphere the other the Western.

Such is the result of the calculation, and it is a somewhat remarkable result when considered in connection with the actual physical features of the globe, and the distribution of land and sea on its surface. But too much confidence must not be placed in it ; many more measurements would be necessary to establish this figure as a reality ; as yet it is merely indicated by the existing observations, and the amount of the eccentricity of the equator shown above is really very minute.

It is to be observed—returning to the spheroidal figure and comparing this new result with that quoted above from the volume of "Comparisons of Standards"—that the effect of the new work in India has been to increase the radius of the equator by 140 feet, and to diminish the polar radius by 226 feet.

There are several short arcs on the European continent which might have been used in addition to the long arcs, but the influence of these on the result would have been almost imperceptible. The details of the American Coast Survey oblique arc are not yet published.

Notwithstanding the immense additions to geodetical measurements and to the data of the problem of the figure of the earth since Bessel's investigations (1841), it is with a good deal of truth that Karl Maria Friederici says that Bessel's results are still universally adopted by scientific men. And this must be considered a very remarkable instance of the influence of a *name*. Bessel was a splendid mathematician ; his works are characterised by great elegance ; and in this case his fame is a set-off against the increase of data subsequent to his time. But Bessel could only use one-fourth part of the present English arc (and the terrestrial measure of this arc as used by him was some 200 feet in error), and one-third of the present Russian arc. In his time the English, Russian, and Indian arcs amounted in all to less than 27° ; now they exceed 57°. Hence Bessel's figure of the earth cannot be considered anything else than obsolete, however excellent it may have been six-and-thirty years ago.

The operations which are being conducted with so much activity on the European continent and in India must shortly put us in possession of great additions to the data of the problem, especially through the agency of the electric telegraph. As a specimen of the precision now attainable in the determination of longitudes by galvanic signals, we may quote the three results obtained at different times and in different ways for the difference of longitude of Greenwich Observatory and Harvard Observatory (Cambridge, Massachusetts). They are as follows :—

	h.	m.	s.
In 1866, by Anglo-American cables	4	44	31·00
In 1870, by French cables to Duxbury	4	44	30·99
In 1872, by French cable to St. Pierre	4	44	30·96

Doubtless there is a certain amount of good fortune in this, but nevertheless the accordance is highly satisfactory.

AN EXPERIMENTAL INVESTIGATION OF THE STRUCTURE OF FLUID COLUMNS WHICH ARE AFFECTED BY SOUND

WHEN a fluid escapes from a contracted opening, it may form a column, which throughout the greater part of its length has the same sectional shape as the opening. This kind of column may be called prismatic.

It may after leaving the opening form an expansion, this expansion being succeeded by another at an angle (usually a right angle) to it ; and this latter by another, and so on. This kind of column may be called segmental (Fig. 1).

1.

An example of the first is obtained when the column proceeds from a true cylinder, truncated at right angles to its axis, and is very difficult to obtain.

A segmental column is easily obtained from the end of a partially closed glass tube.

Segmental columns are sensitive, prismatic columns not sensitive, to sound.

The character of a jet is determined by connecting with a water supply.

The apparatus, Fig. 2, is intended to show the structure of a segmental column. *a*, *b*, *c*, *d* is a piece of cork $2\frac{1}{2}$ in. × 1 in. and 1 inch thick. Pieces of glass tube 2 inches long serve as axes for the corks C C. Each cork is pierced at right angles to its axis to support a jet J. An india-rubber T-piece connects the jets with gas or water supply.

It will be seen that the arrangement permits of the jets being inclined to each other at any angle by the movement of the corks round their axes ; and a lateral adjustment may be obtained by sliding them along their axes.

To make the jets : the middle of a long piece of glass tube is contracted in the blowpipe flame ; when cold a sharp scratch is made in the middle of the contraction, and the tube broken through. Two perfectly equal jets are thus obtained.

Experiment I.—Arrange the jets at an acute angle and connect with a water supply. The segmental column will be obtained. The first (primary) expansion being at right angles to the plane of the jets.

Experiment II.—Keeping the water supply as before, increase the angle of the jets ; the segments will become more marked and the length of the entire column decreased. At a certain angle the primary expansion becomes so great that the cohesion of the

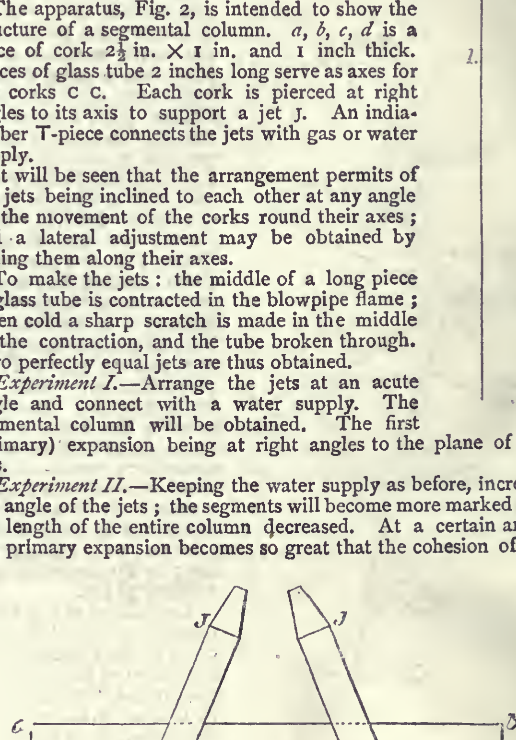

Fig. 2.

different parts will be overcome, and the column be fan-shaped.

The ordinary fish-tail burner furnishes a familiar example of this extreme segmentation.

Note.—As every degree of segmentation may be obtained with suitable inclination of the jets, it follows that a segmental column really consists of two similar ones, meeting at an angle.

Experiment III.—Arrange, as in Experiment I., but connect with a gas supply and ignite. The primary expansion will be obtained but not succeeded by any other. This is readily accounted for. The edges of the expansion, as far as the middle, are receding from each other, and there being no cohesion in gases, they continue to recede, and so the expansion is fan-shaped.

Experiment IV.—Starting with the jets at an angle of about 60° and their ends nearly in contact, lessen the angle and adjust the gas supply, that the flame may take the shape shown in Fig. 3. At a certain point increase of gas will cause the flame to emit a note (usually a very high one), and at the same time commencing somewhere about O[1] there will be an expansion at right-angles to the primary one. A horizontal section of the flame will now have a cruciform contour.

Fig. 3.

Having obtained this musical flame, withdraw the jets through their corks (keeping the same angle throughout). As the distance between them increases the note becomes of lower pitch. With careful attention a very low note may be obtained. At a certain distance the note ceases, but may be restored by additional gas pressure.

Note.—It is evident that the velocity of the gas decreases with its distance from the jet. Hence the greater the velocity the higher the note.

I have shown (NATURE, vol. xv. p. 119) that the velocity of the escaping gas is decreased by ignition, therefore if a certain flame produces a low note the same column unignited will give a higher one. This is found to be the case.

Experiment V.—Having arranged, as in the preceding experiment, reduce the gas supply till the flame ceases to sing. It will now be sensitive to a certain note. Produce this note very near the flame, the flame takes the same shape as when singing (Experiment IV.).

Experiment VI.—Produce a flame tolerably sensitive (Experiment V.). Mount a whistle so that it may revolve round the flame. In two positions, being the ends of a diameter passing through the edges of the flame, the sound will produce no effect.

Note.—It will be seen that the sonorous impulses strike the flame in such a manner that the two columns are thrown into the same phase of vibration. The maximum effect is produced at points at right-angles to the minima. The waves reaching the nearer column first will throw it into a phase differing from the distant one.

Experiment VII.—Select jets of such a size that a flame may be obtained as large as one's hand. At a pressure just below that at which it sings it will be highly resonant.[2]

A sound produced in its vicinity will cause it to resound. When the exciting note has ceased, the sound of the flame will gradually subside; at the same time giving forth higher and higher harmonics of the note.

The sounds, however, are very feeble, and can only be heard at a very short distance. A convenient arrangement for amplifying the sound, is to place the stoppered end of a large gas jar in contact with the ear, and direct the open mouth towards the flame. With a correct adjustment any note within a very wide range will excite the flame, which may emit the same, or some harmonic of it. By whistling an air with the mouth, a rather pleasing accompaniment is heard, and the extreme gravity of some of the flame-notes is certainly remarkable. I have not succeeded in augmenting the notes so as to make this a lecture experiment.

Fig. 4 consists of a cork or other suitable material about 6 in. long, and 1 in. wide and thick. The axis of a jet A is directed to just pass clear of the top of a jet B. A is supported in a cork so that it may approach or recede from B. The end of A is contracted till it will give a flame about $1\frac{1}{2}$ inch long, under the full pressure of the gas mains ($\frac{6}{10}$ in. water).

[1] This corresponds with the intersection of axes of the jets.

[2] A large gas supply is indispensable, and very careful adjustment is required to obtain the most favourable result. A pressure of $1\frac{1}{2}$ inches of water is sufficient.

When tested with water it should show very slight segmentation.

Experiment VIII.—Produce at B the smallest possible flame, and direct the full flame from A, so that the point just passes over the top of B. Extinguish A without turning off the gas. The issuing gas will form a bluish cone beyond B, the space between A and B remaining unignited.

A may now be withdrawn from B till the cone becomes unsteady. If the column has very slight segmentation the distance may be five or six inches. With most jets, however, the limit will be about three or four inches.

This column is exceedingly sensitive. The faintest sound to which it responds will cause the ignited cone to recede towards A.

The greater length, and therefore the greater velocity of the unignited column will be at once noticed (*vide* Experiment IV.)

Experiment IX.—Arrange as Experiment VIII., and remove A just so far, that the cone does not strike back to it. Now very softly produce the responding note. The column recedes and becomes ignited through the whole of its length.

Experiment X.—Replace A by a rather more segmental jet, and obtain the cone. It will be seen that when the cone recedes, it is divided at the extremity more or less perfectly, into two parts.

Experiment XI.—Replace the jet B by a disc of spongy platinum [1] about the size of a halfpenny.

The unignited column causes an annular patch of the platinum to become red hot. When the column is excited the annulus is divided into two spots. The same column, if previously ignited, will not be affected by the same sound.

This forms another proof of the excitability of the unignited column.

In Fig. 5 two equal jets inclined to each other at an acute angle, are fixed in a cork which freely slides in a tube 5 in. × $\frac{5}{8}$ in.

Experiment XII.—Using the apparatus (Fig. 5), slide the cork near the top of the tube and ignite the gas. Slowly lower the cork till a point is reached at which the flame is sensitive. Observe that the base of the quiescent flame in contact with the tube forms a sinuous line, consisting of two depressions and two crests at right angles to each other; and further, that the crests correspond in position with the edges of the primary expansion, and the depressions consequently with the sides.

Note.—When the flame is excited their relative positions are reversed.

Experiment XIII.—Use a low gas pressure (one or two tenths) with Fig. 5, and slide the cork down the tube till the base of the flame becomes unsteady. At a certain point a noise will cause the flame to move from side to side *in the same plane as the jets.* Increase of pressure accelerates the movement.

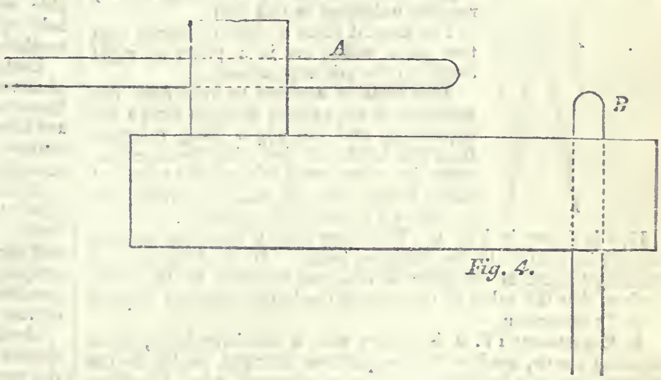

Fig. 4.

Instruments for the production of sensitive flames may be divided into two classes:—

1. Those in which the whole of the gaseous column is ignited.
2. Those in which the column is only partially ignited.

[1] A good substitute for the spongy platinum is obtained by pounding some fine asbestos till quite smooth, moistening with a tolerably strong solution of platinum tetrachloride, moulding the mass into the required shape in a piece of paper, and igniting. The paper burns off and leaves a porous fragile mass. This is alternately soaked in the platinum solution and ignited three or four times, when it becomes tolerably durable.

Class I. *Ignited Columns.*	Class II. *Partially-ignited Columns.*
a. The apparatus described by Prof. Barratt, *Phil. Mag.*, April, 1867.	*a.* Described in Nature, vol. v. p. 30.
b. Described in this paper, Fig. 2, *et seq.*[1]	*b.* Described in a former communication, December 7, 1876.
	c. Described in this paper, Fig. 4, *et seq.*

I. *a* consists of a glass tube with a tapering jet. A V-shaped cut made across the end of the jet renders it more sensitive. If such a jet be connected to a water-supply it will be found to be segmental. If it has the V-shaped groove this will be more marked. The primary expansion lies in the groove in most cases. The only use of the latter is to render the column more certainly segmental.

Fig. 5.

The column being segmental, consists (Experiment II., note) of two streams, one on each side the groove meeting at a very acute angle.

When there is no groove little irregularities in the orifice determine the segmentation of the column. The friction of the long, narrow jet and the ignition of the gas at the orifice retard the outflow, and to obtain a sufficient velocity the gas must issue under a considerable pressure[2] (one or two feet).

When excited it shortens and expands at *right angles to its primary expansion.*

I. *b* has been described (Fig. 2, *et seq.*). The jets meeting at a considerable angle, the column is flattened. It responds in the same manner as the preceding, but the primary expansion being very short, the responding expansion is usually the longer one.

II. *a* consists of a tapering jet placed a small distance below a piece of fine wire gauze. The gas is ignited above the gauze. It is very sensitive, but the intersection of the column by the gauze prevents the flame from taking any well-marked form when responding.

II. *b* is practically the same as the foregoing. The column being surrounded for a part of its length by the closed tube, remains unignited in this part.

The excited flame divides distinctly into two parts, which are in a plane at *right angles* to the primary expansion.

This division appears to arise from the tendency of the excited flame to form a flat expansion, and the edges being reflected from the inside of the tube, because the same jet when used without the tube and under a high pressure, does not divide, but produces a fan-shaped expansion.

II. *c* is shown in Fig. 4. The flame from B keeps the column beyond it heated to the ignition point. It is of interest as showing the use of the gauze in II. *a* and the tube in II. *c*, and further, that the value of the tube in the latter does not depend upon its resonance.

In Experiment IV. it is shown that a sensitive-flame, when emitting a note, sends out an expansion at right angles to the primary one, the same behaviour being observed when the flame is excited by an external sound. It therefore follows that if these actions are conversely related to each other, that a responding flame should emit a note. This will always be found to be the case; but the sound being usually very feeble, may escape observation unless some means be adopted to concentrate it (*vide* Experiment VII.).

The expansion occurs just above the intersection of the axes of the jets. Call these *a* and *b*. The two columns strive for a mastery of direction. *a* overcomes *b* and sends a tongue of flame through the primary expansion, but the partial stoppage of *b* causes an increase of pressure by which in turn it overcomes *a*, and sends a tongue of flame through the other side of the primary expansion, and so on. These movements succeeding each other with very great rapidity in a high note, and gas being highly elastic it is impossible to recognise them separately. Experiment XIII. shows how the impulses may be obtained so slowly as to be individually perceived.

When the gas pressure is so low that the column is quiescent, a sound is necessary to start the operation; and further the sound must so strike the component columns as to give one of them an advantage (*vide* Experiment VI.).

I have only referred to water columns as far as was necessary to illustrate the behaviour of gaseous ones. They should form a subject for separate consideration.

Summary.

1. A fluid column if sensitive to sound consists of two columns meeting at an angle (Experiment II. *note*).
2. The resultant of the two columns is an expansion (Experiments II. and III.).
3. A column so constituted will under favourable conditions emit a note (Experiment IV.).
4. If excited by an external sound, it takes the same form as when it spontaneously emits the sound (Experiment V.).
5. A column excited as in 3 and 4 sends out an expansion at an angle (usually a right angle) to the primary expansion.
6. The component column of a sensitive column must be at such unequal distances from the sounding body that they are not thrown into the same phase of vibration (Experiment VI. and *note*).
7. A gaseous column increases in sensitiveness with the pressure, *i.e.*, the velocity.
8. A gaseous column is lessened in velocity by ignition at its origin (Experiment VIII.). Hence—
9. A gaseous column when ignited is less sensitive than when unignited (Experiment IV.).

R. H. Ridout

[1] Lecomte has previously shown that the fish-tail burner is sensitive.
[2] By making a V-groove across the end of a partially-closed tube, this kind of jet becomes tolerably sensitive at a pressure of three inches

THE AURORA OBSERVATIONS OF THE AUSTRO-HUNGARIAN ARCTIC EXPEDITION, 1872-74, *BY CARL WEYPRECHT*

The Austro-Hungarian Arctic Expedition of 1872–74 was in many respects an unfortunate one. Not only was the first winter occupied with an unintermitted struggle with the ice, which from hour to hour threatened to crush the ship, and rendered it imperative that everything should be in constant readiness for her sudden abandonment, but in the second year this had actually to take place, and, on account of their bulk, valuable records of scientific observation were unavoidably left behind, and among these was the carefully-kept journal of northern-light observations.

Under such discouraging conditions the mass of valuable observations which Lieut. Weyprecht has succeeded in collecting from the meteorological and magnetic journals and other sources, are interesting not only on account of their many positive contributions to our knowledge, but as an example of wonderful scientific industry and devotion.

Spite of the perpetual changes of the aurora, Weyprecht considers that its appearances may be classified under five distinct forms, viz., the *arch*, the *ribbon* or *streamer*, the *rays*, *crown*, and *haze* (*Bogen*, *Band*, *Fäden*, *Krone*, and *Dunst*). His description of these forms differs in several particulars from those common in lower latitudes, so that we may be excused for noticing them at some small length.

Arches (*Bögen*, *arcs*) are of regular form; the highest point closely coincides with the magnetic meridian and the ends cut the horizon at points equi-distant from it. They usually move either northward or southward, rising from the edge of a low dark segment near the horizon, or again vanishing into it. The rim of light which edges this dark segment is probably only a low and distant bow, or possibly the combined effect of all the remoter arches which are melted into each other by distance and perspective. This is the more likely since a bow is never observed to sink wholly below the horizon, but fades into this distant rim, and, conversely, from it, arches frequently arise and separate themselves as they get higher. Not unfrequently the arches sink back to the point from whence they arose; at other times they gradually fade away as they near the zenith, or after they have passed it. Very intense displays never take the form of regular arches.

While in low latitudes the arch is one of the most frequent of auroral forms, in the polar regions this post is occupied by the *ribbon* or *streamer* (*Band*), which resembles a torn and irregular arch, and may take any position or direction, one or both the ends being usually visible above the horizon. It takes the most varied and ever-changing forms, forcibly suggesting a pennon floating on the breeze, doubling and curling on itself in graceful and translucent folds, or again appearing as if torn into shreds blown by the wind. Weyprecht is inclined to believe that the wind actually has some influence on the northern lights, and notes that, after severe and widely-extended storms, the streamers are especially ragged and broken. While in the arch the light intensity changes but slowly, and simultaneously over the whole bow, the reverse is the rule with streamers, in which it varies irregularly, lightening in one place and fading in another. The rapidity of these changes is very varied. Sometimes a band will drift slowly across the northern or southern sky, without change of form or colour, for a long time together, and then suddenly flame up with rapid movement across the zenith to form a crown, to renew its play, or to vanish on the other side. Frequently pieces break off and form new bands, which spread over the whole heavens, and then again fade down to a single band of a new form, or perhaps carry on their game until the dawn drives them from the sky. In most cases the light of the streamers has a peculiar motion, resembling waves which roll continuously from one end of the band to the other. These waves are more intense and move more rapidly in proportion to the activity of the bands themselves. The streamers vary in their appearance, sometimes seeming to consist of a uniform light-material like most of the arches, at others of closely-packed perpendicular rays, with the intervals filled with the same light-material. Between these two extremes are all intermediate gradations. When the rays are visible each brightens as the wave passes over it, but does not change its position except by a slight lengthening, which gives the hopping or dancing motion which, no doubt, is the origin of the term "merry dancers." When, on the other hand, the streamers consist of simple "light-material," the waves cause a brightening and slight undulatory motion of the edge.

Admirable illustrations of these streamers, as they are occasionally seen in lower latitudes, may be found in Prof. Piazzi Smyth's Edinburgh astronomical observations, under the name of "multiple arcs," but they are already approximating to regular arches, from which they probably differ only in distance and altitude. This work also contains most valuable plates and observations of the auroral spectrum, as compared with that of twilight and the zodiacal light. The *threads* (*Fäden*, *rayons*) are fine rays of light directed from the magnetic zenith to the horizon, but not quite reaching either. They occur sometimes singly or in bundles, sometimes pretty uniformly distributed, and are very variable in length. Their breadth rarely exceeds one minute of arc, and they are separated from each other by dark spaces. Their motion is peculiar, and seldom rapid. They lengthen and shorten upwards or downwards, giving the impression that already existing threads are lighted up or fade. They also move slowly from west to east or east to west, and not unfrequently it seems rather that the light is transferred gradually from one thread to another than that the threads themselves actually move.

The threads are evidently in intimate connection with the streamers. Often they stretch from near the magnetic zenith like a fan or a veil of gold or silver threads, of which the streamer forms the broad lower border; singularly, however, they rarely actually reach it, but seem to fade away near its edge, only to reappear with greater brightness in the streamer itself. This phenomenon is seen in the most beautiful way where two bands appear at once, one over the other, and each with its proper fringe of threads, like a silvery veil, falling in the most graceful folds. It is, however, only occasionally that threads and streamer occur in combination, and in the feebler displays it is more usual to see fans of threads, or streamers alone than both at once.

The *crown*, as is well known, is the perspective effect produced round the magnetic zenith, towards which the auroral beams, following the lines of magnetic force, seem to converge. The intensity of the appearance is very variable, and at times becomes such that thousands of short broad flashes dart at once from or towards the centre, while the whole firmament is covered with widespread rays, which lengthen and shorten with a flickering motion. Broad bright flames leap about the centre as if driven by a fiery whirlwind, and all the heavens seem in flames. In general the more brilliant the appearance, the shorter is its duration, and though it sometimes happens that masses of light move for hours about the centre, yet in such cases the brilliancy and the motion are alike feeble.

As a rule a crown is formed whenever an aurora of pronounced form passes the magnetic zenith, *i.e.*, when the beams of which it is composed are parallel with the observer's line of sight. Faint auroræ, however, especially arches with slow motion and no rays, may pass the zenith without forming a crown, and, on the other hand, a feeble crown sometimes becomes visible without the passage of any noticeable band or arch. When, as sometimes happens, the streamer is formed of uniform "light-material" without distinct rays, rays are also absent from the crown, which consists merely of lambent flames flickering round the centre, and resembling those of alcohol burning on a flat surface.

The *haze* (*Dunst*), as its name implies, resembles a faint mist, from which, by moonlight, it is scarcely distinguishable, as its light is never intense.

With regard to *colour*, Weyprecht observed that in bands the red always formed the lower and green the upper part, the middle being whitish. The haze was frequently reddish, but dull greenish seems to have been the prevailing colour, which is compared to that of the electric spark. Most unfortunately the expedition was unprovided with any spectroscope suitable for such observations, so that on this most important point we have no information to record.

The intensity of the light was such that the smallest type was frequently legible, and larger could be read easily. Weyprecht proposes to measure the intensity of the aurora by observation of the legibility of print of different sizes.

With regard to the height of the northern lights above the earth's surface, Weyprecht is strongly of the opinion that they are much lower in the arctic regions than in lower latitudes, but was not able to make any direct measurements. Their brilliancy and distinctness, and, above all, their rapid movements, give the impression of nearness; and the observations of Parry, Farquharson, and others, lead to the same conclusion. On one or two occasions the aurora appeared to be below the light cirrus clouds, which do not attain a maximum height of more than 8,000 metres; but the observation was by no means certain.

Auroræ were also repeatedly visible when the sun was so little below the horizon that the height of the direct sun-rays in the zenith was not more than from six to twelve miles. If, as has been suspected, the auroral light depends on some form of mist for its basis, this would have been rendered visible had the height been such as to bring it into the sunlight; but if, as is generally supposed, it depends on the electrification of rare and transparent gases, this would not be the case; so that it seems difficult to draw any conclusion from these facts. Admitting, however, the conclusion, which is in itself probable enough, that in high latitudes the appearances are lower than with us, it will go far to explain many of the differences which may be noted between Weyprecht's description and what we are accustomed to see. Streamers such as he describes would, if far enough off, and owing their altitude to great elevation, appear like arches, as the lower edge is at an almost uniform height, the windings would disappear with distance, and we should have the appearance of a pretty regular arch of irregular brightness and with beams shooting from it towards the zenith, while the individual threads would be, as is indeed the case, rarely or never visible.

Weyprecht repeatedly observed clouds and mist which took the same forms as aurora, and strongly resembled it; but he does not think a case is made out for any real connection between the two phenomena. The stars, however, are decidedly obscured by an intense aurora, and many observations seem to point to some such connection. Several very interesting ones are quoted by the present writer in the article "Aurora" in the last edition of the *Encyc. Brit.* Weyprecht frequently uses the phrase "light-material" in speaking of the aurora, and it is evident that there must be some material basis to the phenomenon. This, he suggests, may be the minute ice crystals, which are the cause of mock suns and moons, appearances of daily occurrence in the polar regions. It seems certainly possible that these may be projected far above the earth, or even above the atmosphere by electrical repulsion, and may serve as carriers of electrical discharges, which would at once illuminate the particles and arrange them in the lines of magnetic force. If the aurora is really, as

is commonly supposed, an electric discharge in a rarefied gas, it must admit of a very considerable range of density, since it is certain that even in the same aurora, different portions are at very different elevations. In the crown for instance, the beams are almost perpendicular, and must be often of very great length.

The aurora has frequently been supposed to be a sign of coming wind and stormy weather, but careful comparison of the meteorological records failed to establish any such connection. No sound could be attributed to the northern lights.

Weyprecht's observations confirmed the fact that there is a zone of maximum frequency and intensity of auroræ some distance south of the pole, and led further to the conclusion that the zone moves northward towards the winter solstice, and southward again towards the equinoxes. It is of course impossible to observe its course during the summer.

Observations of the daily period gave a maximum at 10 P.M., and a minimum at 11 A.M., which closely coincides with the results of other observers.

No very clear conclusion could be drawn as to a yearly period, since the length of the nights, the cloudiness of the sky, and above all, the before-mentioned shifting of the zone of maximum frequency so complicated the problem.

Want of space unfortunately forbids us to enter into any detailed discussion of Weyprecht's extensive magnetic observations. Many magnetic disturbances were unaccompanied by aurora, and on the other hand, some aurora produced little or no magnetic variation. Those appearances which have an indistinct outline and diffused light, and especially which have no rays and no noticeable motion, scarcely affect the needle; while, on the contrary, those which appear to be low and near, which have distinct contour and rapid motion, and above all sharply defined rays, affect the needle vigorously. Broad darting lightning-like rays, with brilliant colours, red and green, cause the most violent disturbances. HENRY R. PROCTER

UNIVERSITY AND EDUCATIONAL INTELLIGENCE

WE are pleased to find that local schools of science are increasing their facilities for teaching practical chemistry to their students. During the summer the committee of the Birkbeck Institution (the first London Mechanics' Institute) has built a new chemical laboratory, to replace the somewhat inconvenient one which has done service for fifty years. The space available was very limited, but has been made the most of, and nineteen benches have been fitted up in a space of 36 feet by 10½ feet, besides the necessary accommodation for stores, &c. This effort to meet the requirements of students is all the more commendable, on account of the probability of the Institution remaining but a few years longer in its present home. Its success is so great that a new and larger building is absolutely necessary, and the building fund being raised amounts already to nearly a thousand pounds.

SOCIETIES AND ACADEMIES

PARIS

Academy of Sciences, September 16.—M. Fizeau in the chair.—The following papers were read:—On the cause of the periodic movements of flowers and leaves, and on heliotropism, by M. P. Bret.—On a new telephonic transmitter, by M. P. Dupont.—Remarks on a new proposal made with regard to the analysis of milk, by M. E. Marchand.—Description of a new apparatus for the transfer of gases from one vessel to another, by M. A. Blanc. The appatatus is constructed with the special view of avoiding any loss of gas on its being transferred over mercury.—Various communications regarding phylloxera, by MM. E. Fortier and Capbladoux.—On the intra-Mercurial planet seen in the United States during the solar eclipse of July 29 last, by Mr. Swift.—On the observations made of the transit of Mercury on May 6, 1878, at the Imperial Observatory of Rio de Janeiro, after the new method, by M. Emm. Liais.—On the form of the integrals of differential equations of the second degree in the neighbourhood of certain critical points.—On the compressibility of gases at high pressures, by M. E. H. Amagat.—New researches on the physiology of the vesicular epithelium, by MM. P. Cazenove and Ch. Lyon.—Note on the interior temperature of the globe, by Mr. W. Morris.—Note relating to an apparatus named galioscope, by M. A. Boillot. This apparatus is constructed to demonstrate the invariability of the direction of the plane of oscillation of a pendulum.—Note relating to a new thermohydrometer, by Mr. H. Douglas.

September 23.—M. Fizeau in the chair.—The following among other papers were read:—Dissociation of oxides of the family of platina, by MM. Saint Claire Deville and Debray. Osmium and ruthenium combine directly with oxygen, and the product of oxidation is volatile and forms at the highest temperatures. In this they are distinct from the other platinic metals, and come near arsenic and antimony, with which they might be placed among the metalloids. From experiments with oxide of iridium the authors show that, at a temperature below 1003·3°, it is decomposed in free air, and consequently that, at this temperature or any other higher, iridium is absolutely inoxidable in the air.—Memoir on a universal law relative to the dilatation of bodies, by M. Levy. This is designed to prove that the pressure which any body supports can only be a linear function of its temperature, so long as this body does not change its state; in other words, and under a physical form, if any body be heated with constant volume, the pressure which it exerts on the immovable walls of the inclosure containing it, can only increase, rigorously, in proportion to its temperature. This, he thinks, an absolutely rigorous corollary from the two fundamental propositions of the mechanical theory of heat, and of the hypothesis that the mutual actions of the atoms of bodies are directed in lines which join their points of application, and only depend on the distances of these points apart.—Nocturnal variations of the temperature at different altitudes recorded at the observatory of Puy-de-Dôme, by M. Alluard. He has traced, for each month since January, the curves of minimum, maximum, and mean temperatures of the two stations, and it appears that the two curves of minimum temperature often cut each other, both in summer and in winter, so that, often, at night, it is less cold at the top of the Puy-de-Dôme than at Clermont, the difference sometimes reaching five degrees. The curves of maximum temperature do not intersect; they are in general nearly parallel. The temperature at night, then, varies with the height, quite otherwise than during the day. A new meteorological station has been formed about midway between Clermont and the summit of Puy-de-Dôme, the three heights being thus—400 m., 1,000 m., and 1,470 m. It is purposed, too, to take observations on some of the numerous extinct volcanoes (in form of truncated cones) about the Puy-de-Dôme, the object being to study the atmosphere, layer by layer.—Discovery of a small planet at the observatory of Hamilton College, Clinton, by Mr. Peters.—On a new species of curves and of anallagmatic surfaces, by M. Picquet.—On the development of chilostoman bryozoa, by M. Barrois. This he finds *mesoblastic*, the exoderm gives rise to all the organs and plays the part of a veritable blastoderm.—M. Lancy presented a work by M. Ennes, surgeon in the Portuguese army, on "Men and Books of Military Medicine."

THURSDAY, OCTOBER 10, 1878

THE ELECTRIC ARC AMONG THE GAS SHARES

IN Wednesday's *Daily News* we read as follows:—

"Gas shares have been subjected to considerable depreciation owing to the publication of some statements stated to have been made at a meeting in Birmingham. The folly which shareholders exhibit in sacrificing their holdings on the slightest alarm cannot be too strongly deprecated." Among the changes recorded in the official list we find Imperial Continental fell 7; Gas Light and Coke, H issue, $7\frac{1}{2}$; ditto, Ordinary, 5, and so on, and so on.

There is little doubt that some excellent fooling (if fun were the writer's only object) on the part of the *New York Sun* is among the causes of this wonderful exhibition of alarm on the part of gas shareholders. But we doubt the fun. Any man quoting the remark that the sun shines on the evil and the good, would, if he combined candour with perfect knowledge, make an exception in favour of the *New York Sun*. It has a decided predilection for the evil. Nor is this all. Mr. Edison, besides being the most wonderful inventive genius of the age, is one of those rare beings, an American humourist. Indeed, if we are to believe the Western newspapers, those universities and stock raisers beyond Chicago who hastened, after the manner of our own Oxford, to enshrine his name on the rolls of their illustrious men and beasts, did so not because he had benefited mankind or lived laborious days in his laboratory at Menlo Park, but because a word dropped by him had given rise to the rumour that he had just put the finishing-touch to a swearing-machine.

Here is the *New York Sun's* story;—

"Mr. Edison says that he has discovered how to make electricity a cheap and practicable substitute for illuminating gas. Many scientific men have worked assiduously in that direction, but with little success. A powerful electric light was the result of these experiments, but the problem of its division into many small lights was a puzzler. Gramme, Siemens, Brush, Wallace, and others, produced at most ten lights from a single machine, but a single one of them was found to be impracticable for lighting aught save large foundries, mills, and workshops. It has been reserved for Mr. Edison to solve the difficult problem desired. This, he says, he has done within a few days. His experience with the telephone, however, has taught him to be cautious, and he is exerting himself to protect the new scientific marvel, which, he says, will make the use of gas for illumination a thing of the past.

"While on a visit to William Wallace, the electrical machine manufacturer in Ansonia, Connecticut, he was shown the lately-perfected dynamo-electric machine for transmitting power by electricity. When power is applied to this machine it will not only reproduce it but will turn it into light. Although said by Edison to be more powerful than any other machine of the kind known, it will divide the light of the electricity produced into but ten separate lights. These being equal in power to 4,000 candles, their impracticability for general purposes is apparent. Each of these lights is in a substantial metal frame, capable of holding in a horizontal position two carbon plates, each 12 in. long, $2\frac{1}{2}$ in. wide, and $\frac{1}{2}$ in. thick. The upper and lower parts of the frame are insulated from each other, and one of the conducting wires is connected with each carbon. In the centre and above the upper carbon, is an electro-magnet in the circuit with an armature, by means of which the upper carbon is separated from the lower as far as desired. Wires from the source of electricity are placed in the binding posts. The carbons being brought together the circuit is closed, the electro-magnet acts, raising and lowering the upper carbon enough to give a bright light. The light moves towards the opposite end from which it starts, then changes and goes back, always moving towards the place where the carbons are nearest together. If from any cause the light goes out the circuit is broken and the electric magnet ceases to act. Instantly the upper magnet falls the circuit is closed, it relights, and separates the carbon again.

"Edison on returning home after his visit to Ansonia studied and experimented with electric lights. On Friday last his efforts were crowned with success, and the project that has filled the minds of many scientific men for years was developed.

"'I have it now!' he said, on Saturday, while vigorously turning the handle of a Ritchie inductive coil in his laboratory at Menlo Park, 'and, singularly enough, I have obtained it through an entirely different process than that from which scientific men have ever sought to secure it. They have all been working in the same groove, and when it is known how I have accomplished my object, everybody will wonder why they have never thought of it, it is so simple. When ten lights have been produced by a single electric machine, it has been thought to be a great triumph of scientific skill. With the process I have just discovered I can produce 1,000—ay, 10,000—from one machine. Indeed, the number may be said to be infinite. When the brilliancy and cheapness of the lights are made known to the public—which will be in a few weeks, or just as soon as I can thoroughly protect the process—illumination by carburetted hydrogen gas will be discarded. With fifteen or twenty of these dynamo-electric machines recently perfected by Mr. Wallace, I can light the entire lower part of New York City, using a 500 horse-power engine. I purpose to establish one of these light centres in Nassau Street, whence wires can be run up town as far as the Cooper Institute, down to the Battery, and across to both rivers. These wires must be insulated, and laid in the ground in the same manner as gas-pipes. I also propose to utilise the gas-burners and chandeliers now in use. In each house I can place a light meter, whence these wires will pass through the house, tapping small metallic contrivances that may be placed over each burner. Then housekeepers may turn off their gas and send the meters back to the companies whence they came. Whenever it is desired to light a jet it will only be necessary to touch a little spring near it. No matches are required.

"'Again, the same wire that brings the light to you,' Mr. Edison continued, 'will also bring power and heat. With the power you can run an elevator, a sewing-machine, or any other mechanical contrivance that requires a motor, and by means of the heat you may cook your food. To utilise the heat it will only be necessary to have the ovens or stoves properly arranged for its reception. This can be done at trifling cost. The dynamo-electric machine, called a telemachon, and which has already been described, may be run by water or steam power at a distance. When used in a large city the machine would of necessity be run by steam power. I have computed the relative cost of the light, power, and heat generated by the electricity transmitted to the telemachon to be but a fraction of the cost where obtained in the ordinary way. By a battery or steam-power it is forty-six times cheaper, and by water-power probably 95 per cent. cheaper.'

"It has been computed that by Edison's process the same amount of light that is given by 1,000 cubic feet of the carburetted hydrogen gas now used in this way, and for which from \$2.50 to \$3 is paid, may be obtained for

from 12 to 15 cents. Edison will soon give a public exhibition of his new invention."

So much for the *New York Sun*. Although a student of science will have little difficulty in associating the results promised with the discovery of perpetual motion, it is quite probable that Mr. Edison has actually succeeded in doing what he states he has done in his telegram: "I have just solved the problem of the sub-division of the electric light indefinitely." What we wish to point out is that it is one thing to do this and another thing to produce an electric light for ordinary house and street use. Once put the molecules of solid carbon in motion, and just because a solid is in question, the light must be excessive and the expenditure of energy must be considerable.

While it is easy to believe that the future may produce a means of illumination mid-way between the electric light and gas, it is equally easy to see that the thing is impossible without great waste, and therefore cost, with dynamo-electric machines and carbon poles. So long as carbon is employed we shall have much light which, perhaps, can be increased and steadied if various gases and pressures are tried. But streets and rooms full of such suns as these would be unbearable unless we sacrifice much of the light after we have got it. Split up the currrent in the manner so cheerfully described by the New York paper, and the carbon will refuse to flow altogether if an engine of 5,000,000 horse-power be employed instead of the modest one of 500 which is to light the south part of the island. If Mr. Edison has succeeded in replacing carbon he may have turned the flank of the difficulty to a certain extent.

Although, however, we may pity the ignorance of those who act upon such statements as those made by the imaginative *New York Sun*, gas companies may well begin to feel uneasy at the general attention which is being drawn to the electric light as a substitute for gas *if they are prepared to let things alone*. That in one form or other it is likely to be partially adopted in all large cities and at extensive public works seems most likely. It will be one of the lights of the future, but not to the excluding or superseding of gas-light.

Our own columns have repeatedly borne testimony to the success which has attended its introduction into Paris, where it is to be met with at almost every corner, and at one or more of the railway stations. The general testimony of those who are unprejudiced is that at least for wide streets, squares, and open places, its lighting effect is all that could be desired. Every Londoner is familiar with the effect of the display which the enterprising Mr. Hollingshead has placed in front of the Gaiety Theatre, and the glowing contrast presented to the miserable yellow flames of the neighbouring street-lamps; but this contrast exists because the gas is bad and dear. Mr. Hollingshead, in a letter to the *Daily News*, corrects the view of the gas companies, that the electric light must necessarily cost more to produce than gas. His own display, necessarily wasteful, costs four-fifths what gas would, and he is probably correct in saying that with proper management it need not cost more than one half. Moreover, in yesterday's *Times*, Mr. E. J. Reed refers to the case of M. E. Manchon, a large manufacturer at Rouen, who has gone to considerable expense to alter his premises to suit the electric light, and who, even with hired engine power, finds that there is an annual saving of 22·6 per cent. over gas, with infinitely better light and a wholesome atmosphere. Mr. Reed is of opinion that even if the electric light cost more than gas, its advantages are so great, that for the lighting of public places, museums, art galleries, manufactories, &c., he would advocate its general introduction. Even Madrid, one of the most backward cities in Europe, has introduced the light, one great benefit of which, especially in theatres and other much frequented places, is that the heat generated and the contamination of the air is greatly less than in the case of gas.

Let the directors of gas companies do all they can to improve their gas. They may be certain that it will never cease to be required; a considerable splitting up of the electric current is impossible, while the brilliant light that we shall always get when electricity is employed will gradually so raise the *pitch* of illumination that more gas than ever will be used.

THE MEDICAL FACULTIES

THE opening addresses of the various London medical schools always form an interesting episode in the scientific year, and this session they have been even more interesting and have attracted more attention than usual. This is especially the case with the vigorous and trenchant address (published in full in the *British Medical Journal* of October 5) of Prof. Ray Lankester. On another page we reprint a remarkable article from the *Lancet*, in which it is plainly stated that without endowment of research the progress of medicine must soon become impossible in this country; that the work of scientific investigation demands practically the whole energies of a competent man and is incompatible with the necessity of earning a living in any other direction. It is somewhat remarkable that such an article should be published simultaneously with the outspoken address of Prof. Lankester, who aimed to show that the great Universities of this country are faithless to their duty and to the end for which they were established, in not providing for the pursuit of scientific research, in so far at least as that bears on the healing art.

"The work of the medical profession—its function in the community"—he showed, "is to bring into practical use an immense mass of accurate knowledge with regard to the conditions affecting the healthy working of the human body. Accordingly, two distinct kinds of activity—one dependent on the other, one as important as the other—are to be recognised as essential to the business of the medical profession. The one consists in the accumulating of knowledge relating to the human body and to the conditions affecting its health, the sifting of false from true knowledge, the producing of new knowledge; the other consists in the application of this knowledge to particular cases of disease or danger in such a way that action may be taken, avoiding the disease or danger, or alleviating the suffering which results from them.

"There is a most mischievous notion current at the present time," Mr. Lankester went on, "that the first of these lines of work is 'theoretical,' and that the second is 'practical;' and it is not unusual to separate the 'theoretical' from the 'practical' man,

and to speak of the "theoretical" and the "practical" portion of medical studies. "Such a division," Mr. Lankester truly said, "is a relic from the bad old times. Theory and practice in medicine, as elsewhere, go hand in hand. The results of scientific investigation cannot be applied in the treatment of disease by the man untrained in scientific method any more than the delicate tools of a lathe can be used by one who has not himself devised them, or a watch be mended by the aid of a treatise on watch-making."

Mr. Lankester pointed out that in the present unsatisfactory state of the multitude of medical faculties in England, dependent on the voluntary services of busy medical practitioners, medical education must necessarily be defective; and that so far as this is concerned, the wealthy Universities of Oxford and Cambridge have for long most shamefully neglected their duty. As a result of this neglect on the part of our universities, medical education in the last century was a thing almost unknown in England. Those who were desirous of qualifying themselves for carrying on the profession with anything like thoroughness, had to go to Scotland, or Paris, or Italy, where the idea of a university with its various "faculties," has all along been kept in view. The multitude, however, were content with a simple "apprenticeship" to a medical practitioner, while a few latterly took to following the hospital physician round the wards, to take note of the "great man's" receipts. "But as for instruction in physics, in chemistry, in comparative anatomy, in physiology, in the general properties and activities of living things, it had no existence in London, and was not in any way required on the part of the licensing bodies. The English universities meanwhile, which possessed rich endowments for carrying on these studies, allowed jobbery and indifference to convert their ancient medical officer into sinecures." It was from Scotland, where the torch of true university life was kept burning, that an impulse towards the establishment of better things in benighted England came and set men to work in London. The origin of University College was then referred to, it being pointed out that Government, in its caprice, denied the privilege of granting degrees to the vigorous young institution, and conferred it upon a shadowy body, to which it misapplied the title of London "University," a mere *nominis umbra*, and an utter misapplication of the venerable term. However well the London University may have carried out its anomalous duty, we share in Prof. Lankester's profound regret, that the grand old title of "University" should have been in this way completely divorced from the work of study and teaching. The result is that, in this country, not one man in a hundred, even amongst those possessing university degrees, knows what a university is. "The Universities of Oxford and Cambridge, on the one hand, have entirely departed from the old standard, and ought long since to have been checked in their career and reformed by the power which chartered and protected them in their early days; whilst the admirable body which we call the University of London has precisely the same claim to be called a university as has the Archbishop of Canterbury."

Prof. Lankester then went on to show on how wide a basis of scientific investigation and study the medical ar ought to be built; it is the outcome, the final result, of observation.

"This is the spirit," he said, "in which the great universities of Europe, with the exception of Oxford and Cambridge, have fostered the study of medicine. This is the explanation of the existence of chairs of Chemistry, of Physics, of Botany, and of Zoology, in all their Medical Faculties. Such is the nature of his work that the medical man needs instruction and training in all the great branches of physical science; and from time to time the methods of investigation, the modes of speculation and the generalisations with which he has become familiar in the course of these apparently remote studies, render him most efficient service in the attempt to ascertain and to deal with diseased states of the human body. It is thus that a thorough knowledge of the organisation of both plants and animals becomes part of the equipment required by a medical man, but it is even more directly that the progress of knowledge relative to other organisms affects knowledge relative to the human organism. The knowledge of diseased and of healthy conditions of all organisms, all knowledge of living things, including necessarily man himself, forms one compact interwoven body of science termed biology, and upon this directly the medical art is built, in it all medical practice has its foundation."

But in order that the results of scientific research may be applied to the alleviation of human suffering, there must be continued investigation in order to produce new knowledge. "The production of new knowledge," Mr. Lankester justly said, "is a most absorbing and arduous business. Men who have anything else to do except a small amount of teaching can do very little—only a bit here and there—in the production of new knowledge. Men who are earning their livelihood in the practice of a profession can do very little at it. Men who are preparing students for examination all day all the year round can do but little at it. Only men with fortunes, or men who are paid by the institutions especially founded and meant for the production of new knowledge, can be expected to do much in this way. The institutions especially founded and designed for this production of new knowledge, and richly supported by large annual grants of money in the form of salaries and stipends, are abundant on the Continent of Europe; they are the Universities. In London we have no such institution; there is no University of London in this sense of the word. The medical profession in England, though it has eleven "Faculties" in London and other "Faculties" in provincial towns, is almost totally devoid of those splendid opportunities for profound investigation—for the production of new knowledge bearing on medicine—which the appropriation of public money and ancient endowments to the payment of the Medical Faculties in Germany, for instance, provides."

It is certainly, as Mr. Lankester said, at first sight rather astonishing that we laborious, hard-headed Englishmen, the countrymen of Harvey and Darwin, should have to go to Germany for so much of our new knowledge, and that our text-books of science, instead of being provided by the richly-endowed Fellows of Oxford and Cambridge, should to a large extent bear on their title-pages the names of German professors. This surprise

ceases when we are told that the German university system, consisting of twenty-one universities and 1,250 salaried professors, is carried on at an annual expense of more than 600,000*l.*" At the least, half of that sum and half of the number of salaried workers are devoted to the branches of science connected with medicine. "How is it we have nothing of the kind in England? Is it impossible?" The answer is, in Mr. Lankester's words, that "the production of new knowledge cannot go on without the assistance of endowments or their equivalent. It is impossible to name a single case of a man who did not enjoy either a private fortune or an endowment, and yet has added greatly to scientific knowledge. Medicine and the sciences which she protects have most urgent need of endowment for the purpose of supporting men who shall chiefly occupy themselves in the production of new knowledge." Mr. Lankester's words will show how things are managed in Germany :—

"It is a disgrace to English civilisation that a true university — an endowed university, a university in which new knowledge is continually being produced, and in which men are trained for this work of production as the work of their lives—does not exist in London and in each one of our large cities. I can briefly tell you some of the circumstances which have prevented the foundation of such desirable institutions in this country; and I will further indicate to you what we may hope to see done in this direction in the future. But first let me give you a sketch of one of these German universities which we so much admire and envy. I advisedly select one situated in a small town—the University of Heidelberg. Heidelberg is one of the two universities of the Grand Duchy of Baden, Freiburg being the other; whilst at Carlsruhe, in the same state, is an important technical school. The town of Heidelberg numbers but 22,300 inhabitants. The university has 61 professors, and, by the last returns, 834 students. Of these, 23 professors and 106 students belong to the faculty of medicine. The government of Baden, by which the salaries of the professors are paid and their number determined, does not consider that this proportion of one professor to every five students is an excessive proportion on the side of the professorial staff. This university was founded nearly five hundred years ago (in 1386), and, like all the German universities, was remodelled and greatly improved at the beginning of this century, whilst since that time its wants have continually been provided for with ever-increasing liberality by the state government. There are now four faculties—that of Theology, that of Law, that of Medicine, and that of Philosophy. The professors are divided into the ordinary and the extraordinary. The ordinary professors receive a stipend of about 400*l.* yearly, besides their fees, which in some cases bring their incomes up to 1,000*l.* When a vacancy occurs in a professorship the state minister invites the members of the faculty in which the vacancy has occurred to name two or more individuals whom they would recommend for appointment. The faculty meets and the name of a professor in some other university is proposed. He is written to and asked whether he will come; he probably replies that he would require an increased salary and a new laboratory; very usually his terms are agreed to by the state minister on the recommendation of the faculty, and he is installed in the vacant chair. Sometimes, of course, a younger and less known man is appointed at a lower salary. As an example of the way in which these things are managed in Germany, let me give you an actual history of what recently occurred at Strassburg. I quote from an American journal. 'After the transfer of that city to Germany neither pains nor money was spared to make the university a success. For the chairs of the medical faculty rising men were selected, all of whom were known for original research, and had practically proved their ability as teachers and writers. The chair of pathological anatomy was given to von Recklinghausen, one of the most brilliant of Virchow's pupils, who vacated a similar position at Würzburg in order to accept this new position. When the chair of pathological anatomy at Vienna became vacant by the retirement of the veteran Rokitansky it was offered to von Recklinghausen, and the salary proposed was 25,000 *francs* (1,000*l.*), or about three times the usual salary of such a professorship. But the Prussian government was quite as anxious to retain Prof. von Recklinghausen as the Austrian government was to obtain him, and asked him to say what he wanted. His reply was to demand, as the condition on which he would remain, that there should be constructed a large pathological institute, in accordance with his plans, and in connection with the hospital—an institute which will cost something like 50,000*l.*, and will require a change in the fortifications. His demand was acceded to, and he is hard at work now in Strassburg.'"

Prof. Lankester then describes the magnificent arrangement in Heidelberg for carrying on all kinds of research by men whose great business is to add to new knowledge, with the minimum of destruction of any kind. Here, among other well-known names, Bunsen, "the most eminent of living chemists," and Kühne, the physiologist, the author of the text-book as well known in England as in Germany, have their laboratories and class-rooms; and Gegenbaur is the head of the anatomical institute.

Other names equally great in original research in the various departments of science and other towns in Germany could be mentioned. "Berlin possesses laboratories and museums on a palatial scale, and a perfect army of investigators and students supported by State endowments. Leipzig, again, Strassburg, and Munich, are larger and more richly provided than Heidelberg. All the twenty-one German universities, the eleven Austrian, the four Swiss, and six or more Russian universities (I do not speak of those in Scandinavia, France, Holland, Belgium, and Italy), are fitted out in the same way. In all, medicine is being advanced and developed by the never-ceasing production of new knowledge."

"We, in England," as Mr. Lankester goes on to say, "benefit by this knowledge; we, in common with the rest of mankind, reap the rewards won by the activity of these noble corporations; and yet, it is neither more nor less than the fact that we Englishmen do not possess, throughout the length and breadth of our land, a single institution of our own where such work is done." In the three or four institutions where anything like original research is carried on in this country, the endowments are so inadequate as to seriously hinder anything like complete and satisfactory work. "To speak of these institutions as taking the place in this country of the vast machinery and resources of the Medical Faculties of Germany would be about as reasonable as to compare the pleasure-boats on the Lake of Geneva with the British navy."

Prof. Lankester then sketches the state of things which have come to exist at Oxford and Cambridge. These Universities were founded for the purpose of giving education in medicine as well as in theology, and endowment after endowment was made by men anxious that the Universities should fulfil their functions with efficiency;

but through intrigue these magnificent endowments have been almost entirely filched from the purposes for which they were meant, and the property which was thus consigned to the tender mercies of the Church, is now estimated to produce yearly in each University over 300,000*l*.

"For many years the faculties of law and medicine struggled on in Oxford, growing weaker and more neglected in each decade, until now, after 200 years of this usurpation, there is not a single medical student in the place. In Cambridge the story was very much the same, excepting that there the degradation of the medical faculty has never proceeded quite so far as it has at Oxford, and medical studies are now, we have some reason to hope, being resuscitated in that university by the strenuous efforts of Prof. Humphry and Dr. Michael Foster." We take a few instances from Mr. Lankester's address:—At Oxford, shortly before the destruction of its character as a university, the King, Henry the Eighth, had founded a Regius Professorship of Medicine. The office still exists, and is worth about 500*l*. a year, but the present tenant of the office gives no lectures and has no pupils. Linacre, the founder of the College of Physicians of London, Mr. Lankester tells us, "left to Merton College in Oxford (in the reign of Henry the Eighth) a piece of land, the rental of which was to pay a lecturer in medicine. Within 100 years the office was abolished, and the money converted to the private uses of the Fellows of the College. Confiding benefactors came forward last century and put down their money, in the hopes of promoting medical study in Oxford. But they did not know—and at the present day you cannot make people believe—how shameless and unprincipled were the bodies to whom they entrusted their money. Lord Lichfield bequeathed 200*l*. a year for the reading of clinical lectures in the Radcliffe Infirmary to the students in medicine of the University. The office is now held by the Regius Professor of Medicine, but no lectures are given. About the same time, Matthew Lee confided money to the care of the governing body of the cathedral house of Christ Church, for the payment of a teacher of human anatomy, and to buy subjects for his demonstrations, but no such teaching is given; the money is applied to other purposes. Dr. George Aldrich, in 1798, left 9,000*l*. for similar purposes, but, at the present day, the bequest bears no fruit for the benefit of medicine."

These are only a few instances of the scandals connected with the history and present condition of our great universities, mainly owing to their complete subjection to clerical influence. The colleges, instead of being lodging-houses for poor students, as they were intended to be, were converted into boarding-schools, into which the Fellows received the sons of the landed gentry and wealthy citizens as pupils, on condition of certain payments. To quote Prof. Lankester:—

"The fees demanded by the College-Fellows increased at last to such an extent, and the expense of residing in one of these boarding-houses became so great, that the universities entirely ceased to be popular or national institutions in function, though they were so in foundation. They became the exclusive possession of the clergy and the wealthy classes, and so they remain at the present day. Long ago, students ceased to seek the lecture-rooms of Oxford and Cambridge for the purpose of serious study or professional training. Whilst the Scotch farmer's lad can earn enough in the fields during summer to keep him during a winter's session in the University of Glasgow or Edinburgh, whilst all classes of the community contribute to form the student-world of the German Universities, Oxford and Cambridge, under the influence of clerical domination, have become simply 'finishing schools for young gentlemen' (I quote the words of Prof. Max Müller). Men of moderate means—that is to say, the majority of our fellow-countrymen—now only go to Oxford or to Cambridge with the view of sharing in the scholarships and fellowships, which are annually distributed there by competitive examination. In their whole tenour, purpose, and being, these places are as different as they possibly can be from their quondam sisters the universities of Germany."

What Prof. Lankester insists upon is the establishment of a fully-developed and amply-endowed Medical Faculty in both Cambridge and in Oxford, and, still further, the establishment of one or two such faculties in London. We are glad to think that there is an immediate prospect of a great development of the Medical Faculty at Cambridge, where already experimental physiology, human anotomy, and clinical medicine are taught and prosecuted with energy. There is indeed some prospect that in the course of years, when men with a better spirit have sway in both universities, they will be brought to fulfil all the functions for which they were originally established; and we trust that Prof. Lankester's address may act as the little leaven in the minds of all who heard or may read it, and that gradually not only professional men but the constituencies generally will wake up to a realisation of the immense benefits which are the nation's birthright, but from the enjoyment of which it has for so long been barred.

Prof. Lankester then urges that one, or at most two, medical faculties should be established under the University of London.

"In this way," he concludes, "we might have in London, each provided with ample laboratory, museum, and assistants, two professors of physiology, one of surgical anatomy, one of comparative anatomy, one of embryology, one of botany, one of pathological anatomy, one of pharmacology, one of hygiene, one of forensic medicine, two of chemistry, one of experimental physics, and others of the history and practice of medicine, of surgery, of midwifery, and of psychiatry. The maintenance of such a staff, with their laboratories and assistants, would require an endowment of 20,000*l*. a year, whilst 100,000*l*. would have to be sunk in providing the necessary buildings. This proposition appears Utopian, but all I have to say further in defence of it is this, that in Berlin, Vienna, Leipzig, and other continental cities the thing is done, and on a more costly scale than I have here suggested.

"When such medical faculties as I have sketched to you exist in Oxford and in London, England will have begun to do her duty by the great profession of medicine. Until then we are but hangers-on of foreign nations; until then we reap where we did not sow, we gather where we did not straw. Until that time I earnestly beg every man who enters on a medical career to remember that he is joining the cause of a profession deprived of its heritage, and to make it his business to reinstate medicine in her seat, and to secure the restitution of her possessions."

Prof. Lankester is not only Professor of Zoology at University College, but a Fellow of Exeter College, Oxford: so that he speaks with full knowledge, and

not as an outsider, who might be accused of ignorance and of interested motives. The subject which he has thus brought prominently into notice concerns the highest welfare of this country and the place which she holds among the cultured nations of the world.

MILLER'S CHEMISTRY

Elements of Chemistry, Theoretical and Practical. By William Allen Miller, M.D., LL.D. Revised by Charles E. Groves. Part II. *Inorganic Chemistry.* (London: Longmans and Co., 1878.)

THE number of editions through which this part of the late Dr. Miller's work has passed and the high position it has attained as a Text-book of Inorganic Chemistry render the work of the reviewer almost superfluous, and we have now only to notice what improvements or additions may have been made in the present edition.

The revision of the volume just published has been entrusted to Mr. C. E. Groves, whose position as sub-editor of the Chemical Society's *Journal* renders him particularly fitted for this work, by reason of his being constantly brought into contact with communications upon the more recent discoveries in the science.

The order in which the various elements and their compounds are discussed, as we are told in the preface, remains the same as in the last edition, this order commencing with the least complex compounds and finishing with those of a more complicated nature. Hydrogen is first studied as the standard of atomic weights, densities of gases, &c., and as affording a good example of an electro-positive element; it is followed by the monatomic but electro-negative element chlorine, subsequently by oxygen as illustrating the diatomic condition, boron illustrating the triatomic, carbon the tetratomic, nitrogen the pentatomic, and sulphur the hexatomic. We have thus presented to us in the first chapters of the work the consideration of seven typical elements and their compounds, which tends to give the reader in a simple manner a general idea of the scientific arrangement of the other elements which follow them in their respective groups.

We rather regret that Mr. Groves has thought it necessary to retain boron in its position as the typical element of the triatomic group to the exclusion of nitrogen, taking that latter substance as the illustration of the pentatomic group. Our reasons for saying so are, that boron is not so well known to the student as nitrogen, nor does it possess a hydrogen compound like ammonia; its atomicity, therefore, must be shown by its chlorine compound, thus destroying the similarity with the other types, which in the first four groups are illustrated by their compounds with hydrogen. Had nitrogen been taken as the type of triatomic bodies, phosphorus would then of course have replaced it as the example of a pentatomic element. Farther, by taking nitrogen as the type of pentads, as is done in Chapter x., a little confusion, we think, is liable to be produced in the mind of the beginner; as immediately after the consideration of that body as a pentad, he proceeds to consider ammonia where nitrogen is not *pentatomic* but *triatomic.*

Many of the more recently-discovered non-metallic compounds have been added to the work, and to some parts a considerable amount of new matter has been contributed by Mr. Groves in the description of recent experiments, as in Dr. Frankland's work on the luminosity of flames, &c. The metallurgy of iron, also, which is very fully described, occupies a considerable portion of the part devoted to the consideration of the metals, but not, however, to the exclusion of other important matters connected with these bodies. Mention is also made of the two recently-discovered metals gallium and davium.

Competing as this work must necessarily do with other large and recently written text-books, we should have liked to see a little freshening-up given to some of the diagrams, the apparatus in some of the illustrations appearing of rather an antiquated form. As an illustration of this point we might give the diagram illustrating the manufacture of sulphuric acid on the small scale, as shown in Fig. 322. A considerable improvement in the letter-press has, however, been introduced by printing the headings of the paragraphs in larger type than has hitherto been used; this, combined with the references to the original papers from which the information contained in the work has been taken, will, we think, prove of great value to the more advanced student.

The work throughout bears evidence of thorough as well as careful selection in regard to the new material introduced, and we think the publishers are to be congratulated on obtaining the services of such a conscientious worker as Mr. Groves for the revision of this standard text-book.

OUR BOOK SHELF

A Glossary of Biological, Anatomical, and Physiological Forms. By Thomas Dunman. (London: Griffith and Farran, 1878.)

MR. DUNMAN'S glossary is the result of an attempt "to place before the student the pronunciation, derivation, and definition" of the terms "usually employed in that department of biological science which treats of animal life, as set forth in standard text-books of Huxley, Carpenter, Foster, Flower, and others," and will be a useful book, no doubt—the more so as there is no other work covering exactly the same ground. At the same time the derivations and definitions appended to the terms are not always quite correctly given, particularly as regards the zoological terms. The order of birds called "Dromæognathæ" was so named by Prof. Huxley because the Tinamous which compose it have the palate formed like that of the ostriches (*Dromæus*, an Emeu)—not from the Greek "dromaios" directly. "Holothuridea" is from Holothourion—a good Greek Aristotelian word—and has certainly nothing to do with "thuris," a little door, as Mr. Dunman would have us believe. A more probable derivation is θοῦριος, *furiosus*, because the Holothuria burst in pieces when touched. There are no such Greek verbs as "πνέυσω, I breathe" (given under Pharyngnopneusta), or "πτόω, I fall" (given under ptosis). The correct Greek derivations in these cases are πνέω and πίπτω. "Egesta" is not formed from "*egestio*—getting-rid-of," but is simply the participle of *egero*, meaning such things as are got rid of. Nor are Mr. Dunman's explanations of the purely anatomical terms always faultless, although there is less occasion for criticism here. The "*ligamentum nuchæ*" is formed of elastic not of "connective" tissue. The "sectorial" tooth of the dog is certainly not definable as the fourth premolar, for the dog has no fourth premolar. The "tri-

facial pair of nerves" are not so called because they arise by three pairs of roots, but because they send three main branches to different parts of the face. We doubt "amnion" having anything to do with "amnos—a lamb." It is an old classical word for one of the fœtal membranes, as may be seen by reference to a lexicon. Lastly, we may remark that "hernia" is very imperfectly, not to say incorrectly, described by Mr. Dunman.

It would not be difficult to pick more holes in Mr. Dunman's volume—which, however, in spite of some defects, will be serviceable to the persons for whose aid it is designed.

The Native Flowers and Ferns of the United States. By Thomas Meehan. Illustrated by Chromolithographs. Issued by Subscription. (Boston: L. Prang and Co., 1878.)

THIS book is intended to be "an anthology in the truest sense of the word," and aims at culling the most beautiful, interesting, and important from the vast number of plants found in the enormous region ruled by President Hayes. Further, it is not merely scientific; a familiar treatment is adopted so that the cultivator and mere lover of flowers may derive both profit and instruction. The first parts which we have received lead us to think that the editor has hit upon a good working way of carrying out his intentions. The text is very readable, the printing is most excellent, and the name of Prang as publisher tells those who know that the chromolithographic part cannot be excelled.

Magnetism and Electricity for Schools and Science Classes. By George Porter. (Belfast: William Mullan and Son, 1878.)

SO many school manuals of Electricity and Magnetism have appeared during the last ten years, particularly since the establishment of the South Kensington Science Examinations, that one is led to question the advisability of adding to their number. The existing manuals are, as a rule, as complete and comprehensive as works of their size and price can be, and until new facts are discovered, or new methods of treating old facts are in vogue, we do not see the necessity of multiplying such text-books. The work before us does not present any special feature. It is suitable for low Forms in a Public School, and for the elementary examination in Electricity at South Kensington. It is cheap and sufficiently illustrated, but occasionally insufficiently explicit for young boys. The chapter on Terrestrial Magnetism might with advantage be somewhat enlarged, and would be distinctly improved by the addition of one or two simple figures.

La Revue Magnétique, Organe du Cercle Electro-magnétique de Paris. Rédacteur-en-Chef, H. Durville. Nos. 1, 5, 6. (Paris, 1878.)

WE have received the above three numbers, the first of which was published on April 16. Acting upon the saying *ex pede Herculem*, we give an extract or two from the "A nos lecteurs." "Il ne faut pas considérer le magnétisme comme une panacée universelle; mais son emploi peut rendre d'immenses services à l'humanité. Sans remplacer complètement la médecine, il peut la seconder puissamment, dans les maladies même les plus désespérées. Quand il sera bien compris de tous, dans la plupart des cas le père de famille deviendra le meilleur médecin de ses enfants; le frère traitera son frère; l'ami, son ami; et tous travailleront alors au progrès de tous. En publiant la *Revue Magnétique*, nous avons l'intention de rallier tous les éléments qui divergent encore autour de la doctrine; d'affermir celle-ci sur une base inébranlable, et de découvrir les secrets les plus cachés de la nature pour les utiliser au profit de l'humanité. . . . Nous ne reculerons devant aucun sacrifice; nous répondrons à toutes les objections qui nous seront posées, et nous insérerons avec empressement les articles qui nous seront adressés. Flétrissant de toutes nos forces le charlatanisme partout où nous le rencontrerons; combattant les abus de toutes nos forces, nous enseignerons le MAGNÉTISME comme une œuvre de science et de charité." These are fine professions. There are articles on magnetism and somnambulism, an unpublished manuscript of Mesmer, and other short notes. A paper by the Editor, entitled, "Les Nombres considérés dans leurs rapports avec les Sciences occultes et les différents Cultes," runs through all the numbers, and contains much curious matter, which, from the style in places, reminds us of the *brochures* we have noticed in these columns from the pen of the Comte L. Hugo. To an outsider the journal appears strange; it carries on its face a good motto from Bossuet: "La Vérité est un bien commun; quiconque la possède la doit à ses frères."

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to ensure the appearance even of communications containing interesting and novel facts.*]

The Zoological Record

DR. HOEK'S complaint in NATURE, vol. xviii. p. 569, that not much care had been taken in the record as to zoological papers published in the Netherlands in 1875 and 1876, doubtless appears well grounded to himself from his locally restricted view, but, when analysed, is scarcely of sufficient importance to call for more than an expression of regret that a certain percentage of omission and error must inevitably occur in any large undertaking. No one of the recorders fancies that his work is complete, and the omissions of any one year are constantly supplemented in the following volumes, our best thanks being given to those who will take the trouble to put us right.

The copy of Dr. Hoek's paper, "Die Zoologie in den Niederlanden," sent for our guidance, was duly received after the usual delays, and I beg to thank him publicly for his forethought and kindness in presenting it. It bore the date 1877, and, if it had contained matter to be recorded, would be included in the volume for that year now being compiled. But, being bibliographical only, its use is as an index to the different recorders. It contains notices of eighty-seven papers, on no particular branch of zoology, and referring to no particular locality, but merely published in the Netherlands in 1875 and 1876. Of these eighty-seven papers, I find only seventeen not given in the records for those years; and, as no less than ten of these were published in the latter year, the delay of one volume only is caused by the omission. One of the seventeen (by Benjamins) is purely histological, and not in our scope; four others (by De Man and Winkler) are palæontological, and two at least of the rest are of the most unimportant nature (by De Graaf and Everts). The remainder are one in Mammalia (but more correctly to be referred to Vermes), one in Pisces, two in Mollusca, one in Insecta (Lepidoptera), and five in Crustacea, so that the charge of want of care, when shared by the recorders of these divisions, appears founded upon a very slight basis.

A certain querulousness in Dr. Hoek's last sentence is probably to be attributed to the incompleteness in the record of Crustacea, the five omissa in which are unfortunately all his own papers. (I observe that four papers of Dr. Hoek's on Crustacea are included in the records for 1875 and 1876, though apparently not the same as these.) Dr. von Martens, the recorder of that division, would, however, be the first to deplore this, and to feel the loss to himself as a worker; and his reputation for accuracy and fidelity is too great to suffer from this *lapsus*.

It may be mentioned, also, that two of the omissa are contained in Academical Inaugural Dissertations (which it is needless to explain are practically never published); and that another of them is published in the papers of the Zeeuwsch Society of Sciences (Middelburg), which, to say the least, are not in the hands of every working naturalist in this country.

October 1 E. C. RYE

Intra-Mercurial Planets

THE places sent you of the objects which I designated by (*a*) and (*b*) in my observations during the total eclipse on July 29 were derived from the hurried readings of the circles made immediately upon my return from the Eclipse Expedition, in order to be able to answer numerous inquiries addressed to me for information in regard to these observations. Subsequently I made a careful determination, and the readings of the circles and all the data for a definitive reduction of the observations were communicated to astronomers in this country and in Europe. These have probably already come to your knowledge and need not be repeated here.

The only outstanding question in regard to the place of the star which I designated by (*b*), is whether any disturbance of the telescope by the wind is to be feared. The position was marked on the hour circle first, and but a moment was occupied in passing from the eye-piece to the place where this was done. The wind was blowing fresh from a direction south of west, but our telescopes were, as you know, well sheltered by the semi-circular ledge behind which we observed. My own instrument was near the ledge on the west, and was more completely protected than any of the others, and hence it became desirable to know whether any such disturbance of their instruments was noticed by Prof. Newcomb, Commander Sampson, and Lieut. Bowman, who observed near me. Accordingly, I addressed letters to these gentlemen for information upon this point. Prof. Newcomb read the circles of his instrument for a pointing made at about the same instant, which proved to be on a fixed star, and there was no disturbance whatever of the position of his telescope. Lieut. Bowman says that there was no disturbance of his instrument by the wind during the totality, and Commander Sampson says that his assistant, Dr. Dewitt, who pointed for him while using the spectroscope, did not notice any disturbance.

These reports might be regarded as conclusive upon the question which I raised, when I came to reduce the observations, since otherwise the star (*b*) could not be ζ Cancri. If the totality had only lasted a few seconds longer I might have moved out to ζ Cancri, and by observing it also there would have been no uncertainty whatever. But I hardly realised at the time the possibility of there being two planets near the sun, and being sure of one, I gave more attention to it. The record of (*b*) was made just before the sun reappeared. In fact, the sun came out just as I turned to go to the eye-piece again, and anxious to have Prof. Newcomb's telescope also directed on (*a*), I ran across to where he was observing, but his telescope being then directed toward a suspicious object, for which he was reading the circles, it could not be disturbed. Returning to my own instrument it was too late to re-observe (*b*) or to find ζ Cancri, and I could not then determine whether the object observed was a stranger or not. It was very much brighter than I expected to see ζ Cancri, judging from the appearance of δ Cancri, which I had seen in a preceding sweep.

In order to obtain further evidence as to the stability of the instrument, I have made careful experiments with it, clamped as it was then, and I find that the danger feared has no significance whatever. During the present week, also, there have been days when the wind was blowing very strong from the same direction as on the day of the eclipse, and I have placed the telescope in the position as to direction in which it then was, but fully exposed to the wind, and it has remained hours at a time thus exposed without the pointing being sensibly changed. I conclude, therefore, that the object which I designated by (*b*) is also a new star.

I have lately examined, on two mornings, the stars in that part of Cancer, and my recollection of the appearance of the stars (*a*) and (*b*) being still vivid, I have compared, with the same telescope and magnifying power, the stars which I then observed in the vicinity of the sun. The moon shining brightly in the west, and the bright twilight in the east, gave a sky-illumination in some respects similar to that at the totality of the eclipse. By observing when the approaching daylight had extinguished the light of two small stars which I saw on July 29 east of the sun, so that they were just visible in the telescope as they were on that day, I proceeded to compare the light of θ and ζ Cancri. As a result of this examination, I am convinced that I under-estimated the magnitudes at the time. I think that (*a*) must be classed as good fourth magnitude, and (*b*) as third magnitude, if not brighter. JAMES C. WATSON

P.S.—I have begun some calculations, but being pressed just now in the preparation of elements, perturbations, and ephemerides of ten or twelve of the minor planets for the *Berliner Astr. Jahrbuch*, I have not yet progressed very far. It is probable that M. Gaillot will have worked up all the material available for this. J. C. W.

Ann Arbor, September 21

Sun-spots and Weather

IN the last number of NATURE (p. 567) there is a very interesting communication from Mr. Fred. Chambers of Bombay. He shows that the barometric pressure at Bombay when graphically exhibited for a series of years, gives a curve which is very similar to the sun-spot curve, and he remarks that the barometric curve lags behind the sun-spot curve particularly in the years of maximum sun-spots. He argues that the sun is probably hottest at times of maximum sun-spots. I have grounds for thinking that I found traces of a somewhat similar relation in discussing the daily range of the thermometer at Kew Observatory, although the results obtained were not so definite as those of Mr. Fred. Chambers.

When, however, we go from the meteorological to the magnetical influences of the sun we find a very marked and well-known relation between the sun-spot areas and the magnitude of the diurnal range of declination,—this diurnal range being unmistakably greater when there are most spots. Here also the lagging behind comes prominently out whatever may be its cause.

Mr. Frederick Chambers quotes the following remark made by me (NATURE, vol. xvii. p. 326):—

"It is nearly, if not absolutely, impossible from observations already made, to tell whether the sun be hotter or colder as a whole when there are most spots on his surface. The sooner we get to know this the better for our problem."

I ought here to mention that in these words I referred more particularly to *direct* observations of the heating effect of our luminary. I ought also to state that the fundamental importance of such observations was impressed upon me by the remarks of a very distinguished physicist, who considers that a persistent and well-organised attempt should be made to determine by means of actinometric observations whether our luminary is in reality of variable heating power.

We know a good deal about sun-spots, although not nearly so much as we ought, but we know next to nothing about the variations (if any) in the direct heating effect of the sun. I can only here repeat what I said before, that "the sooner we get to know this the better for our problem." BALFOUR STEWART

Manchester, September 27

Cyclones and the Winter Gales of Europe

THE following figures may interest some of your readers as a contribution to the theory put forward in NATURE, vol. xvi. p. 505, regarding the meteorological effects of variations in the intensity of solar radiation, and of the consequent changes in terrestrial temperature.

According to this theory, the high temperature which generally coincides with sun-spot minima should have the effect of increasing the steadiness and velocity of the prevailing winds of the globe, whilst, at the opposite epoch of the solar cycle, the weakness and unsteadiness of these currents ought to give rise to heavy rain on the coasts and islands of the tropics, and to facilitate the generation of cyclones, which (as has been shown by Messrs. Blanford and Eliot in the case of the Bay of Bengal), are most probably caused by the condensation of aqueous vapour over the place of its production. If this view of the action of variations in temperature upon the convection currents of the atmosphere be the true one, it follows that the south-westerly gales of Europe should be most frequent and powerful at times when the cyclones of the West Indies are least frequent. This is borne out by the accompanying table, which shows the number of hours in each year during which the wind-velocity in the British Isles exceeded thirty miles, as compared with the number of cyclones in the West Indies, according to Poëy. The figures in the second line are taken from the *Quarterly Weather Reports*, and represent the averages of the annual totals for Valencia, Armagh, Glasgow, Aberdeen, Sandwick, Falmouth, Stonyhurst, and Kew. These are the only stations which give a continuous register for the six years in the table.

	1869	1870	1871	1872	1873	1874
Hours of high wind (British Isles) ...	714	570	537	679	571	658
Cyclones (W. Indies)	0	7	3	0	1	?

The period covered by the table is too short to afford any ground for a definite induction; but, as far as they go, these figures afford *primâ facie* evidence in favour of the theory.

I may add that the probability of this relation between the gales of the temperate zones and the cyclones of the tropics has been pointed out on purely speculative grounds by Mr. E. D. Archibald, in a pamphlet on the rainfall of the world, recently published by him in India. S. A. HILL

Allahabad, September 11

Magnetic Storm, May 14, 1878

IN the *Bulletin Mensuel* of the observatory of Zi-ka-wei, near Chang-hai, China, the following interesting remark occurs in the number for May, 1878:—

"Durant le mois de Mai, une seule perturbation a été enregistrée par le magnétophotographe; elle commença le 14, à 2h. 20m. de l'après-midi, et se termina 24 heures après; ce jour-là la déclinaison, par extraordinaire, ne présenta pas d'oscillation diurne normale, mais de très-nombreuses petites oscillations comme le bifilaire."

On examining the photographic trace of the Stonyhurst magnetograph I find that the only magnetic storm in May last commenced on the 14th at 6h. 4m., and lasted rather more than twenty-four hours. The longitude of Zi-ka-wei being 8h. 15m. 38s. E. of Stonyhurst, the storm began at the same time at both stations. The character of the movement was also identical, for the only disturbance at Stonyhurst from 6 A.M. until 4 P.M. was a tremulous motion of the declination and horizontal force magnets.

The storm was at its height at midnight, when all the magnets were much disturbed, and the vertical force magnet was thrown completely off its balance.

It is impossible to obtain more than the roughest outline of a magnetic storm from hourly readings, but even this slight datum from China shows a general agreement in the declination curves during the storm at these two distant stations.

The *Monthly Record* of the Melbourne Observatory also mentions the same magnetic disturbance, which commenced there at 4 P.M. on the 14th, and lasted until 8 A.M. on the 17th. Melbourne lies 9h. 39m. 54·8s. E. of Greenwich, and therefore 1h. 34m. 10s. E. of Zi-ka-wei. We thus see that the Zi-ka-wei storm commenced at 3h. 54m. Melbourne time: it was therefore simultaneous at the three observatories.

Stonyhurst Observatory, September 27 S. J. PERRY

Winds and Currents in the Pacific

THE occasional prevalence of westerly winds and of currents setting east in the intertropical portion of the Pacific, has such an important bearing on the possible eastward migrations of the Polynesians that I think the following, which I take from the *Samoa Times* for April 20, is worth recording in NATURE.

The brigantine *Ryno* is reported as having arrived at Apia, Samoa, on April 16, from the Tokelau, or Union Group. She was among those islands from March 1 to April 11, and, while there, she "experienced a succession of strong westerly and north-west winds, with high sea and frequent squalls and much rain, which made sad havoc amongst the vessel's canvas. Capt. Bower states that, when off Tokelau, he found a strong current setting to the eastward at the rate of two miles per hour. The *Ryno* left Tokelau on April 11, had fine E.S.E. weather, and no current whatever." S. J. WHITMEE

Blackheath, September 27

Blackburn's Double Pendulum

I TRUST I may be pardoned for observing, in reference to Prof. A. M. Mayer's description of the curves produced by Blackburn's Double Pendulum (NATURE, vol. xviii. p. 594), that a typical series of those curves was placed before the readers of NATURE in the year 1871 (vol. iv. pp. 310, 370), in illustration of a paper of mine on "Pendulum Autographs."

Prof. Mayer adheres to the funnel and sand as the mode of laying the curve on paper. The sand-trail thus left is necessarily rather coarse, and cannot be conveniently preserved. A more delicate and more enduring trace, in ink, can be obtained by the use of a tubular glass pen, as described by me in the paper above-mentioned. Only the increased friction makes it necessary to use a heavier bob. HUBERT AIRY

Circulating Decimal Fractions

As a supplement to the interesting properties of circulating decimal fractions which have been published in two recent numbers of NATURE, I give you the following, which I think is sufficiently curious to merit attention:—

If the decimal fraction equal to $1 \div n$ *recur in a cycle of* $n - 1$ *digits, the average value of the digits is constant, viz.,* $4\frac{1}{2}$ *for all values of* n; *in other words, the sum of the digits of the cycle is* $4\frac{1}{2}(n-1)$.

For example,—

$$\tfrac{1}{7} = \dot{1}4285\dot{7},$$

and $(1 + 4 + 2 + 8 + 5 + 7) \div 6 = 27 \div 6 = 4\frac{1}{2}$.

Again,

$$\tfrac{1}{17} = \dot{0}58823529411764\dot{7},$$

and $(0 + 5 + 8 + 8 + \text{\&c.}) \div 16 = 72 \div 16 = 4\frac{1}{2}$.

The theorem is easily established from the two facts (1) that $1 \div n$, $2 \div n$, $3 \div n$, ... have the same digits in their cycles, and (2) that the sum of $1, 2, 3, \ldots, n-1$ is $\frac{1}{2}n(n-1)$.

The properties of circulating decimal fractions have been often studied from the time of Wallis downwards, and very probably those lately and now brought forward have been noted before, but have lain entombed in some out-of-the-way corner since. However, until a full index to mathematical literature is prepared, or exhaustive monographs on special departments like this are written, such resurrections are very desirable.

If either of your two previous correspondents on the subject would care to undertake a full examination of it I should be glad to furnish him with my quota of references to the extent of ten or a dozen, and, I have little doubt, other readers of NATURE would give like help. THOMAS MUIR

High School of Glasgow, September 23

[Mr. Muir's theorem is practically contained in the result that the two halves of the period are complementary, whence the sum of the figures is equal to half as many nines as there are figures in the period.—ED.]

An Old Map of Africa

EARLY in the year 1870 I visited the vineyard of Mr. J. L. Cloete at Constantia, near Cape Town.

Among other things of interest Mr. Cloete showed me an old map of Africa done, I think, in Amsterdam. This map had been in the possession of his family from time immemorial. My acquaintance with the geography of Africa was too slight to enable me to pronounce upon its accuracy, but I was greatly surprised to see marked upon it several large lakes and many rivers in the region now so well known to us through recent explorations.

In the critical study of this subject I have thought that a knowledge of the existence of this map, if it be as I remember it, might prove of value. C. F. GOODRICH,

Torpedo Station, Lieut.-Commander, U.S. Navy

Newport, Rhode Island

[We would refer Commander Goodrich to our article on Old Maps of Africa, in NATURE, vol. xviii. p. 149.—ED.]

Earth Pillars

A LETTER in your issue for September 26 (p. 569) refers to miniature earth pillars seen in the Tyrol. But there is no need to travel out of the country to obtain these mimic representations, at any rate on a moderate scale. Twice I have found them, formed by the drops from railway bridges, upon bare clays; and once in a half-finished building, in a sand-heap containing numerous pebbles. Evidently the heavy drops and the protection from driving rain favoured the result. One of the bridges, between Shepton Mallett and Wells, Som., covered Lias clays, protected by cinders, &c. The other instance, the bridge on the new North Approach just outside York Station, is the more interesting in its mimicry of the original Botzen earth pillars, since small boulders and pebbles in the glacial clays form the caps and shoulders in the Lilliputian columns.

September 28 J. EDMUND CLARK

White Swallows

Mr. Herbert W. Page, in Nature, vol. xviii. p. 540, refers to the rare occurrence of a white *Hirundo riparia*.

I may mention that two white swallows of that species were captured in a high bank of sand at Hungryside, on the Forth and Clyde Canal, by Mr. Martin, of that place, in August, 1876, which I exhibited at a meeting of the Natural History Society of Glasgow, August 26, 1878. Both birds were white all over, with the exception of a brown tinge on the back of one of them. Mr. Stevenson, in his "Birds of Norfolk," vol. i. p. 342, mentions a light cream-coloured variety got at Eaton in July, 1861, and another at Weasenham in the following September.

Glasgow, September 27

Secondary Lunar Rainbow

During the very stormy and unsettled weather we had about a fortnight ago, I was one of a party of friends on a visit at a country-house near Huntly, about forty miles from this, who were witnesses, on the evening of Sunday, 15th inst., to a very striking, and, as a friend well versed in meteorology has since informed me, very uncommon phenomenon. It was that not only of a complete and brilliant primary lunar rainbow with colours, but also, a few minutes later, of a complete and well-defined, but, of course, less brilliant, *secondary* bow. No trace of colour could be observed on the secondary, but, inside the primary, the space seemed, in contrast with the faint moonlight, even more brilliantly and uniformly illuminated than I recollect ever to have seen it within a solar rainbow. The time was about eleven o'clock, and the centre of the bows, therefore, bore about W. or a little to the N. of W.

Aberdeen, September 30

BONE CAVES IN STYRIA[1]

1. TWO prehistoric implements, found some years ago in the "Badel" Cave, near Peggau, in Styria, are preserved in the Museum of the Johanneum, at Gratz. Count G. Wurmbrand has lately conducted an exploration of this cave. The floor is formed for the most part of a layer of fragmentary stalagmite, about seven centimetres thick, resting on a loam, with bones and gravel, forty-three to seventy centimetres thick. A peculiar laminated and very compact loam, permeated by a blackish substance (*pyrolusite*) lies on the rocky bottom. In the loam have been found abundant bones and teeth of *Ursus spelæus*, undeterminable remains of rodents, a canine of a stag, bones gnawed by *hyæna*, &c., but no human remains or relics.

2. In a cave on the north slope of the Erzberg, east of Wildalpe, in Upper Styria, Dr. A. Redtenbacher has found abundance of bones and teeth of *Ursus spelæus*. All these bones, except the phalanges, were broken; and the long ones of the extremities were split longitudinally.

3. On July 1 of this year, Dr. R. Hoernes and Dr. R. von Fleischhaker visited the Drachenhöhle (cave of Dragons) near Mixniz, about 1,292 (Austrian) feet above the town, and extending 1,440 feet into the rock, with an entrance 90 feet high and 72 feet wide. The floor of the cave is mostly covered with reddish-yellow cave-loam; but rock-fragments abound within the entrance. The superficial loam had been searched long ago. The inner parts of the cave, accessible only by ladders, were nearly untouched. On the day mentioned, numerous remains of *Ursus spelæus*, both young and adult, fragments of jaws with teeth, single teeth, long bones, ribs, phalanges, &c., were soon found. Some of the teeth and bones in the terminal fissure of the cave could have been brought there only by moving water. No other animal but the cave-bear was represented by the remains met with.

In the portion of the cave next the entrance, a still untouched layer of fragmentary stalagmite, including angular pieces of rock (some very large) was found beneath an accumulation of rock-fragments. Underneath it is an irregular dark-brown and nearly black stratum, about 15 centimetres thick, containing charcoal and partially burnt bones; and in a brown loam, immediately beneath, similar objects were abundant. These bones, differing from those of the yellowish loam of the inner cave, by their greater consistence and dark colour, belong mostly to *Ursus spelæus*, and a few to an undetermined ungulate. The long bones are nearly all broken. Among these dark-coloured bones are phalanges, cervical vertebræ, and the lower portion of a right humerus measuring 16 centimetres between the condyles, which must have belonged to a colossal individual. The connection of the cervical vertebræ (the atlas bearing traces of fire), and the presence of several other bones of this individual (as well as those of smaller ones) lead to the conclusion that it was brought into the cave after being killed, and prepared there for the food of the cave-folk. No implements were found.

OUR ASTRONOMICAL COLUMN

The Satellites of Mars.—The results of the complete reduction and discussion of the Washington observations of the satellites of Mars, undertaken by their discoverer, Prof. Asaph Hall, have just been published by the United States Naval Observatory. The observations of the outer satellite *Deimos* extend from 1877, August 11, to October 31, and those of the inner one, *Phobos*, from August 17 to October 15. On November 7 and 12 the satellites were looked for, but could not be seen. In treating these observations with the view to the determination of the most probable orbital elements of the satellites, Prof. Hall assumes in the first place that their paths are circular, and by a graphical projection finds the angle between the orbit-plane and the plane perpendicular to the line of sight, as well as the angle of position of the major axis of the ellipse into which the circular path is projected. The resulting elements are then compared with the observations, and elliptical elements deduced from the resulting differences between calculation and observation, both for position and distance, by means of equations of condition. Thus the following values of the elliptical elements have been obtained from the Washington observations alone:—

Epoch 1877, August 28·0 Greenwich Mean Time.

	Deimos.	Phobos.
	h. m. s.	h. m. s.
Period of revolution	30 17 53·86	7 39 15·07
Semi-axis major at distance unity ...	32″·3541	12″·9531
Ascending node on equator	48° 5′·7	47° 13′·2
Inclination to equator	35° 38′·7	36° 47′·1
Angle between the lines of nodes and apsides	40° 53′·6	45° 30′·4
Distance from node at epoch	357° 30′·5	285° 20′·2
Eccentricity	0·005741	0·032079

It will be seen that the planes of the orbits of the satellites are nearly coincident with the equator of Mars, the ascending node of which for the above epoch is in 47° 56′, and the inclination 39° 45′. Prof. Hall considers the elements to be determined with tolerable accuracy, with the exception of the periodic times, which remain to be decided within closer limits from the observations of another opposition; nevertheless they are sufficiently exact to carry forward an ephemeris to 1879. The eccentricity in the case of *Deimos* is so small that for most purposes of calculation circular elements will suffice. In the case of *Phobos*, Prof. Hall thinks the eccentricity has a real existence, every comparison of distance with the circular orbit confirming it.

The mass of the planet deduced from the measures of *Deimos* is $\frac{1}{3095313}$, and from those of *Phobos* $\frac{1}{3078456}$, that of the sun being taken as unity; the adopted mean value

is $\frac{1}{3093500}$. The latest value of the mass resulting from theory is that given by Leverrier (*Annales*, vol. xi. p. 3), viz., $\frac{1}{2812526}$.

Prof. Hall compares his elements with the observations made at other observatories, of which those of Cambridge, U.S., Glasgow, U.S., Pulkowa, and Mr. A. Common, of Ealing, were the most successful. The magnitudes of the satellites, free from the glare of the planet, were estimated at about 12 and $11\frac{1}{2}$, *Phobos* being the brighter of the two. On October 15, when their distances from the centre of the planet were respectively 23″ and 57″·5, they were of nearly equal brightness. Prof. Hall further remarks : "The chief difficulty of observing these satellites is on account of the brilliancy of the planet. At their elongations at opposition in 1877, they appeared to me brighter than the outer satellites of Uranus and much brighter than Hyperion, and on October 31 Deimos resembled Umbriel, the second satellite of Uranus, which, at elongation, is fainter, I think, than any other satellite."

With the angular values of the mean distances given above, the real distances of the satellites from the centre of their primary will be for *Phobos*, 5,800, and for *Deimos*, 14,500 miles ; the former, from the rapidity of its motion (it performs more than three revolutions in the Martian day) will appear to rise in the west, meeting and passing the outer moon, and setting in the east, and it will have a horizontal parallax amounting to 21°.

Prof. Hall has definitively adopted the names proposed by Mr. Madan, of Eton, in the columns of NATURE.

THE SATURNIAN SATELLITE, TITAN.—The following are the approximate times of conjunction of the great satellite of Saturn, with the perpendicular to the plane of the ring, during the next month, at which times occultations by the planet, or transits over its disc take place. The elements used are very nearly those of Bessel, but with a somewhat larger ellipticity of the planet.

	G.M.T. of conjunction. h.	Angle of position. °	Distance from Saturn's centre. ″	Saturn's polar semi-diameter. ″	
Oct. 8	13·9	4·2	8·17	8·69	On disc ?
,, 16	5·7	184·3	7·32	8·64	Occulted.
,, 24	11·7	4·3	6·53	8·58	On disc.
Nov. 1	3·5	184·4	5·91	8·50	Occulted.
,, 9	9·6	4·4	5·42	8·40	On disc.

WINGLESS INSECTS OF THE FALKLAND ISLANDS

WHILST on an excursion to Port Darwin, in the Falkland Islands, during the visit of H.M.S. *Challenger* to that group, I found at Darwin Harbour, Choiseul Sound, some insects which are of considerable interest, since, as I believe, they are closely allied to those of Kerguelen's Land. Amongst them were a gnat, practically wingless (Tipulidæ), and a fly with rudimentary wings. The gnats were found crawling on the rocks on the sea-shore, in sheltered places, and also on the sunny, sheltered side of a fence composed of a peat bank, with furze growing on the top of it. They run quickly, and, when in danger, draw up their legs and drop in order to escape, and they are not by any means easy to catch amongst the grass.

The flies were found only on the sea-coast, in hollows under overhanging slabs of the sandstone rocks, sheltering themselves in crevices. They have short wings, which they seem to use in jumping, and they spring nimbly, like fleas or small grasshoppers, and are difficult to catch. On comparing specimens of these flies with specimens of *Amalopteryx maritima*, one of the flies of Kerguelen's Land, with rudimentary wings, described by Mr. Eaton (Rev. E. A. Eaton, the *Entomologist's Monthly Magazine*, August, 1875), I have little doubt that they are very closely allied to this species, and to be referred at least to the same genus. Dr. Kidder describes the habits of the Kerguelen *Amalopteryx* as closely similar (J. H. Kidder, M.D., *Bulletin United States National Museum*, No. 3, 1876, ii. p. 52). Von Willemoes Suhm found a species of the same genus in Marion Island, and we all observed the fly at Kerguelen's Land as well as the wingless gnat which Mr. Eaton has named *Halyritus amphibius*, and which lives on the Kerguelen sea-shore amongst sea-weed constantly wetted by the tide. It would be interesting if the Falkland Island gnat proved allied to the Kerguelen one on further examination.

I found one beetle with wings at the same locality in the Falklands, and one wingless species. All the Kerguelen beetles are wingless. Two genera and all the species of that island are endemic (Mr. C. O. Waterhouse, *Entomologist's Monthly Magazine*, August, 1875, p. 50). The close connection between the Fuegian flora and that of the far distant Kerguelen's Land is well known from the investigations of Sir Joseph Hooker. It is interesting to find a further connection in the insects. The four wingless flies of Kerguelen's Land are assigned by Mr. Eaton to four new genera. I believe, though I am no entomologist, that the Falkland Island and Marion Island fly will come under one of these, and possibly further search may prove the existence of representatives of some of the other genera in Fuegia or the Falklands. I see from the "Histoire Nat. des Insectes Diptères" of the Suitesa Buffon, the only authority immediately at hand, that a wingless gnat, *Chionea araneoides*, is found in Sweden in woods on the snow throughout the winter, whilst two flies with rudimentary wings, *Apterina pedestris* of France and Germany, and *Myrmemorpha brachyptera* of Spain, exist in Europe. These merely as examples. Prof. Westwood tells me many other such diptera are known to entomologists, and he has shown me a specimen of a wingless fly, *Borborus apterus*, which occurs in England.

Exeter College, Oxford H. N. MOSELEY

SUN AND EARTH

THE Meteorological Reporter of the Bombay Presidency, Mr. F. Chambers, at the end of his recently-published report for 1877-78 gives us the first results of some important researches which he has not yet been able to complete, owing to want of clerical assistance. In a brief sketch of the meteorology of the Bombay Presidency in 1876 prepared for the Bombay Administration Report for 1876-77, he showed that the abnormal meteorological conditions which produced the famine of 1877 were of the same type as those which produce the usual alternations of seasons, and therefore are attributable to similar causes.

A commencement was made some time ago with the discussion of the Kurrachee wind observations. One of the most important results already obtained is that the numerical relation existing between the abnormal wind and abnormal barometric movements is exactly similar to the relation between the *annual* variations of the wind and barometer leading to the same conclusion as above, viz., that most of the abnormal variations of weather in India are due to causes which are similar to, if not identical with, those which produce the normal variations. The comparison of the normal and abnormal barometric movements at different stations points decidedly in the same direction, and Mr. Chambers believes that further investigation will prove this to be a general law, affecting perhaps all abnormal meteorological variations which are not cyclonic. He adds :—

"The fact that a famine has been raging in China, at the same time that one has ravaged Southern India, does not appear to be without its significance, in pointing to

other than local causes of the meteorological disturbances which produce famines. Indeed, the inference that most of the unusual variations of weather in tropical climates are induced by corresponding variations in the *absolute* heating power of the sun, in the *same manner* that the seasonal variations are induced by those changes of heating power which depend on the relative *motions* of that body, seems almost irresistible, if it may not be regarded as already partly proved. The importance of this conclusion, if true, will be readily admitted, for it will be at once apparent, that if the absolute variations of the sun's heat are fitful in their occurrence, and do not obey definite periodical laws, it will perhaps never be possible to predict by more than a few days in advance the unseasonal variations of weather induced by them, while if such laws can only be discovered, the possibility of our being able to predict their consequences is equally certain.

OCCURRENCE OF FOSSILIFEROUS TERTIARY ROCKS ON THE GRAND BANK AND GEORGE'S BANK

AMONG the most important results of the investigations made by the party connected with the United States Fish Commission, stationed at Gloucester, Mass., during the present season, is the discovery of fragments of a hitherto unknown geological formation, apparently of great extent, belonging probably to the miocene or later tertiary. The evidence consists of numerous large fragments of eroded, but hard, compact, calcareous sandstone and arenaceous limestone, usually perforated by the burrows of *Saxicava rugosa*, and containing in more or less abundance fossil shells, fragments of lignite, and in one case a spatangoid sea-urchin. Probably nearly one-half of the species are northern forms, still living on the New England coast, while many others are unknown upon our coasts, and are apparently, for the most part, extinct. From George's Bank about a dozen fossiliferous fragments have been obtained, containing more than twenty-five distinct species of shells. Among these one of the most abundant is a large thick bivalve (*Isocardia*) much resembling *Cyprina islandica* in form, but differing in the structure of the hinge. This is not known living. *Mya truncata*, *Ensatella Americana*, and the genuine *Cyprina* are also common, together with a large *Natica*, a *Cyclocardia* (or *Venericardia*) allied to *C. borealis* (Con.), but with smaller ribs, *Cardium islandicum*, and also various other less common forms. These fragments came from various parts of the bank, including the central part, in depths varying from 35 to 70 fathoms, or more.

From Banquereau, N. S., we received one specimen of similar rock, containing abundant fragments of a large bivalve, and about a dozen other species, among which are *Fusus* (*Chrysodomus*) *decemcostatus*, *Latirus albus*, Jeff. (?), unknown species of *Turritella*, &c. From the Grand Bank two similar specimens were received. One of these, from thirty-five fathoms, lat. 44° 30', long. 50° 15', contained numerous specimens of *Cyprina islandica* in good preservation.

In gathering these specimens from the fishermen and working out the specimens Mr. W. Upham has been very active. It will probably be possible hereafter, when these specimens shall have been more fully examined, and more obtained, to give a pretty long list of species, especially from George's Bank.

At present it appears probable that these fragments have been detached from a very extensive submerged tertiary formation, at least several hundreds of miles in length, extending along the outer banks, from off Newfoundland nearly to Cape Cod, and perhaps constituting, in large part, the solid foundations of these remarkable submarine elevations.

A. E. VERRILL

THE BALLOON EXPERIMENTS AT WOOLWICH

THE military balloon experiments at Woolwich have been so far successful, that last week an aëronaut was lifted some 700 feet, to a height, therefore, sufficient for reconnoitring purposes. There is nothing of novelty in this, as a matter of aërial navigation, although it is the first instance, we believe, of any one in this country being raised from the earth by the agency of pure hydrogen, but it is, nevertheless, something to have achieved in the circumstances under which Capt. Templar has been working. Everybody knows that hydrogen is gifted with extraordinary lifting power, just as every chemist is aware that the gas may be produced in the way Capt. Templar produced it, namely, by passing a jet of steam over iron turnings. But the problem under solution was not to send up a hydrogen balloon so much as to discover whether the thing could be done in a haphazard fashion, and with such simple means as an army in the field would be provided with. It is one thing to make hydrogen in the laboratory, and another to make a sufficient supply of it just whenever the commander of an army may order a balloon reconnaissance to be made.

Capt. Templar has practically proved that this can be done. He requires a supply of steam, an improvised furnace of some sort, and a tube filled with iron turnings; given these, he can provide hydrogen sufficient to lift a scout high into the air. The tube at present employed by Capt. Templar is six or eight inches in diameter, and some half-dozen feet long; it is filled loosely with iron turnings and placed in a furnace where it becomes red hot. Steam is now passed through the tube, and hydrogen issues forth, the oxygen from the decomposed steam going to form ferrous oxide. So completely do the iron turnings do their work under these circumstances, that not only is the surface of the metal acted upon, but it is oxidised well-nigh throughout.

Naturally enough, the hydrogen comes away with a good deal of vapour, and, if pure gas is desired, some desiccating arrangement will have to be employed; but so far Capt. Templar has used none. His balloon, which is of lawn, dressed with boiled oil and glue, will contain about 10,000 cubic feet, but last week not more than 9,000 feet of hydrogen was introduced. The gas was generated from the tube at the rate of something like 1,000 cubic feet per hour, and there can be little doubt that, during the long period of filling, a large quantity of the vapour that was mixed with the hydrogen condensed, and ran out of the balloon in the form of water. Pure hydrogen should have a lifting power of 70 lb. per 1,000 feet, or perhaps a little more, but it is hardly likely that gas produced in a rough-and-ready fashion in the field will possess this degree of buoyancy. Still, Capt. Templar was successful in lifting balloon, aëronaut, ballast, and 700 feet of rope—for the ascent was a captive one—by means of 9,000 cubic feet of hydrogen, prepared in the way we have mentioned.

Another point is worthy of note in connection with the experiment. The fabric of the balloon kept the hydrogen imprisoned for a much longer period than had been anticipated. A dozen hours scarcely impaired the buoyancy of the balloon, and by adding yet another waterproof coating it is anticipated that the balloon will remain inflated for four-and-twenty hours.

The next step will be to discover how far it is possible to compress hydrogen so manufactured into cylinders for conveyance in transport waggons, so that a supply of hydrogen may be at hand whenever an ascent is determined upon in the field. Capt. Templar is sanguine of compressing the gas to a fourth of its volume, and thus decreasing its bulk considerably, when the balloon-train is on the march. How far this is practicable experiment only can prove.

THE WEATHER CASE, OR FARMERS' WEATHER INDICATOR[1]

Description

STAND facing and look at the weather case. Now: The right of the case is at your right hand; the left of the case is at your left hand.

The pointer or index at the top of the case (No. 1) slides on the brass arc; it is known as the "Sunset Barometer Index," and indicates, when set by the figures to which it points on the "Main Barometer Scale," which is just below it, the reading of the barometer at the time of the sunset yesterday.

The "Main Barometer Scale" (No. 2) exhibits all the barometric readings likely to be used with this instrument.

The pointer (No. 3) just below the "main barometer scale" is called the "mean barometer index," and indicates, when set, the mean or average reading of the barometer at the place at which the instrument is set and for each separate month. When the barometer reads above or below this reading at any place, such reading is said to be "above the mean" or "below the mean" for that place in that month. This index is set once for each month in the year.

When the barometer pointers go toward the right from this mean or average reading, the barometer is said to be "rising." When the barometer pointers go toward the left from the mean or average reading, the barometer is said to be "falling."

The mean barometer reading for each district for each month is stated in the *Farmers' Bulletin*, or can be had by application to this office.

The long brass hand over the glass face of the barometer is known as the "long pointer," and indicates, by the figures of the "main barometer scale" to which it points when set, the reading of the barometer when last set.

The black pointer on the face of the barometer under the glass face is known as the "short pointer, and indicates the existing pressure of the atmosphere at any time the instrument may be examined.

To Read the Barometer

If the observer stands facing the barometer the "short pointer" (black) moves toward the right as the pressure of the atmosphere (or weight of the air) increases, and to the left as the pressure of the atmosphere (or weight of the air) diminishes. The "long pointer" (brass) should be moved by the turning screw so as to coincide with, or exactly cover, the "short pointer" (black). The barometer is now set for reading, and the "barometer reading" is found by reading from the left to right on the "main barometer scale" from the lowest figures (or readings) on that scale to that exact division or mark upon that scale to which the "long pointer" points or which it covers. The inches and hundredths of inches are marked on the scale. The inches and hundredths are counted from left to right, or in the same direction as the hands of a watch move, and they are counted in the same way as the hours and minutes on a watch-face are counted. The inches and hundredths are written down, if they are to be written, in the same manner as dollars and cents are written, thus: one dollar and seventy-five cents; that is, one dollar and seventy-five hundredths of a dollar would be written $1.75, or one and seventy-five hundredths; $29.35, twenty-nine dollars and thirty-five hundredths. The "long pointer" pointing on the "main barometer scale" to twenty-nine inches and thirty-five hundredths, the barometer-reading would be twenty-nine inches and thirty-five hundredths of an inch, and would be written "29.35 inches," and so for other readings.

[1] Circular issued by the Signal Service of the United States Army—communicated by General Myer, Chief Signal Officer.

Rain Winds and Dry Winds

There are for each place and for each month two kinds of winds:—

First—Winds which, blowing from certain directions, are at that place and in that month more likely than any other winds to be followed by rain. These are called "rain winds."

Second—Winds which, blowing from certain directions, are at that place and in that month less likely than other winds to be followed by rain. These are called "dry winds."

The "rain winds" and the "dry winds" for each district and for each month are stated in the *Farmers' Bulletin*, or can be had by application to this office.

The wind direction for any day or time must be seen and taken at each place or station by a vane as well located as practicable.

The "wind disc" (No. 8) consists of a brass circle, on which slide freely two arcs—a red arc, called the "dry-wind arc" (No. 9), and a blue arc, called the "rain-wind arc" (No. 11). In the centre of the disc is a pointer, turning with a turning-screw, and called the "wind-disc pointer" (No. 10). Around the disc are letters to show directions, as N for north, E for east, NE for north-east, &c.

The wind disc is made ready for use as follows:—If, for instance, the *Farmers' Bulletin*, or other report, states that, for any district or place, and for any month, "winds blowing from south or east, or from directions between those points, are found to be the winds most likely to be followed by rain, winds blowing from north or west, or from directions between those points, are found to be the winds least likely to be followed by rain"—or, in other words, "winds blowing from east or south, or from directions between those points, are rain winds. Winds blowing from north or west, or from directions between those points, are dry winds;" then, if the instrument is to be used in that month and in that district or place, the rain-wind arc No. 11 (the blue) is moved on the brass circle until one end of the arc is at the letter E, which stands for "east," and the other is at the letter S, which stands for "south;" the dry-wind arc No. 9 (the red) is moved on the circle until one end of that arc is at the letter N, which stands for "north," and the other is at the letter W, which stands for "west." The arcs remain as they are thus placed for the whole of the month.

At the beginning of the next month the rain-wind direction and dry-wind direction must be located for that month, and the arcs must be again moved on the circle in the same manner until the rain-wind arc and the dry-wind arc touch, respectively, with their ends, the letters for the points named for the rain-winds and the dry-winds for that month. The arcs then remain so placed for that month—so for each month of the year.

Now, when the wind disc is thus ready, and on any day, the weather case is to be used. (1) The direction in which the wind is blowing is seen by a vane. It is noticed from what direction the wind is blowing, as from the north, south, east, &c. (2) The wind disc pointer (No. 10) is moved by the turning-screw to point to the compass-letters on the disc, or between them, showing as nearly as practicable by those letters the same direction, *i.e.*, that *from* which the wind is blowing when observed. If this pointer, so set, points at either of the ends of either arc, or any part of either arc, it shows, if it so points at the *red* arc, that the wind is at that time in the *dry*-wind direction, or is a *dry* wind; if it so points at the *blue* arc that the wind is at that time in the *rain*-wind direction, or is a *rain* wind.

The hour is noted by a clock or watch, and the time at which a rain wind or a dry wind commenced to blow, or was first noticed, is written down.

It must be also noticed if the wind shifts, as from blowing from a rain direction to blowing from a dry direction, or

DALLASTINT

is blowing from such direction as not to be within either arc.

The length of time for which the wind has blown continuously from a rain direction or a dry direction is of importance to be considered with other local signs and indications.

The pointer and scale (No. 5) on the right of and below the barometer are called the dry-wind time-record, and the pointer (No. 7) is called the "record-pointer," and indicates, when set, the length of time the wind has been blowing continuously from a "dry" direction, by the figures showing the number of hours on the scale to which it points.

The pointer and scale (No. 4) on the left of and below the barometer are called the rain-wind time-record, and the record-pointer (No. 6) indicates, when set, the length of time the wind has been blowing continuously from a "rain" direction, by the figures showing the number of hours on the scale to which it points.

The record pointer on the rain-wind time-record (No. 6) is always turned by the thumb-screw, and set pointing at the figure 0 on the scale when the wind is not blowing in the rain-wind direction. In the same way the "record-pointer" on the dry-wind time-record (No. 7) is always set pointing at the figure 0 when the wind is not blowing in the dry direction.

When in actual use, the hour at which the *wind-disc pointer* has been set is carefully noted. When the weather case is next examined, the wind-vane is again noticed, and the wind-disc pointer again *examined* or adjusted. If it still continues to point at any part of the same arc as before, the number of hours which have elapsed since the last setting and during which the wind-disc pointer has been so pointing is noticed, and the record-pointer on either the rain-wind time-record or dry-wind time-record is turned to show the *number of hours* the wind has been thus noticed as blowing from the *rain* direction or from the *dry* direction, as the case may be. This proceeding is repeated every time the instrument is set. It can thus be seen at a glance whether the wind is, or not, blowing in a rain-wind or a dry-wind direction, and for how long it has been so blowing. Whenever, on noticing the wind-vane, it is seen that the wind has shifted, the wind-disc pointer is set accordingly If it now points at neither arc, or points to the different arc from that at which it pointed at its last setting, the time-record pointer on the rain-wind time-record or dry-wind time-record (whichever may have been in use at the last setting), is turned to point at the figure 0 (zero).

The wind-disc pointer and the time-record pointer ought to be set thrice daily at least, early in the morning, at noon, and at sunset.

The sunset disc (No. 12) consists of a circular disc, one half of which is coloured red and one half of which is coloured blue. The disc turns upon a central turning-screw in such manner that half of the disc shows through a semi-circular opening in the face of the weather-case. The sunset-disc is set as follows:—At the exact time of every sunset the western sky and the character of the sunset is carefully observed. The examination ought to be minute and careful, lasting for about fifteen minutes. If the sunset sky is clear or red, or markedly what is known as a "fair weather sunset"—a sunset such as is generally held to indicate a clear or fair day to follow on the next day, a day on which it will not rain—the sunset-disc is turned by the turning screw until the semi-circular opening shows all red. The sunset-disc, thus turned, is described as set for a "fair weather sunset."

If the sunset sky (the western) is cloudy or foul, or markedly what is known as a "foul weather sunset," a sunset such as is generally held to indicate foul weather to follow on the next day—a day on which it will rain—the sunset-disc is turned by the turning screw until the semi-circular opening shows all blue. The sunset-disc thus turned, is described as set for a "foul weather sunset." If the appearance of the western sky and the character of the sunset are neither markedly those of a "fair weather sunset" or of a "foul weather sunset," but such as to leave the observer in doubt how to style it, the sunset-disc is turned to show half red and half blue, or "doubtful." The sunset-disc, thus set, is described as set for a "doubtful weather sunset."

The term "fair weather sunset" expresses such condition of the sky, particularly the western, and such character of the sunset, as is considered to indicate a fair day, a day on which it does not rain, for the day ensuing.

The term "foul weather sunset" indicates that the appearances are such as to presage a rainy day, a day on which rain falls, for the ensuing day.

The term "doubtful weather sunset" indicates that the conditions are such as to leave the mind of the observer in doubt as to what the sunset presages for the following day. The indication is considered to be for the period of time from the "sunset" of the day on which the character of the sunset is examined until the "sunset" of the following day.

Dry-bulb and Wet-bulb Thermometers

In the lower part of the weather case there are two thermometers, a dry-bulb thermometer (No. 13) on the left-hand side of the case, and a wet-bulb thermometer (No. 14) on the right-hand side.

The dry-bulb thermometer is like any other thermometer, and shows by its readings the temperature of the air.

The wet-bulb thermometer is one, the bulb of which is kept constantly moist by the water passing up from the glass reservoir, through the wicking which covers the thermometer bulb.

The readings of the dry-bulb thermometer and those of the wet-bulb thermometer, are more and more unlike, or farther and farther "*apart*," as it is called, in proportion as the air contains less and less moisture; that is, is becoming *dryer*.

The readings of the dry-bulb thermometer and those of the wet-bulb thermometer become more and more *alike*—are nearer and nearer together—in proportion as the air contains more and more *moisture*; that is, is becoming saturated or *wet*.

By the side of the dry-bulb thermometer (No. 13) is the dry-bulb pointer which slides on the brass slide (No. 15). By the side of the wet-bulb thermometer is the wet-bulb pointer which slides on the brass slide (No. 16). In the centre of the case is the "dry- and wet-bulb scale," marked on the paper on which is the central brass slide-bar (No. 19), and on this slide move the dry-bulb keeper (No. 17) and the wet-bulb keeper (No. 18). To set the thermometers examine first the dry-bulb thermometer and move the "dry-bulb pointer" (No. 15) on the slide until the outside point is exactly level with the top of the mercury in the thermometer—as near to it as practicable. Examine next the wet-bulb thermometer, and move the wet-bulb pointer (No. 16) on the slide until the outside pointer is exactly level with the top of the mercury in the wet-bulb thermometer, or as near to it as practicable, then turn to the "dry- and wet-bulb scale," and on the "central brass slide-bar" (No. 19) move one of the keepers until it touches, as nearly as possible—is on an exact level with the inside pointer of the "dry-bulb pointer," then move the other keeper until it touches, as nearly as practicable—is on an exact level with the inside pointer of the "wet-bulb pointer." The thermometers are now set, and the difference between their readings can be known by counting on the "dry- and wet-bulb scale" the number of degrees between the keepers.

When the thermometers are examined and set again, following the same plan, it will be easily seen whether the

"keepers" are, when set, *farther apart* than they were at the previous setting, or whether they are, when set, *nearer together* than at the previous setting.

If they are farther apart the thermometers are said to be "separating." If they are nearer together the thermometers are said to be "approaching." Other things being equal, the thermometers show, when they are "separating," that the air is becoming more dry—one sign of approaching fair weather. The thermometers show, when they are "approaching," that the air is becoming more moist or damp—one sign of approaching rain.

The reservoir at the bottom of the weather case ought to be kept half filled always with pure water. The wicking must be kept clean and changed occasionally—say, once in each month.

Uses of the Weather Case

The weather case is not intended to be used independently of the official weather reports. It is to be used always in connection with them. The weather case is for the purpose of supplementing the official reports by showing the local instrumental indications, and giving other information. It is intended especially for use at Farmers' Post Offices and places reached with difficulty by the printed reports. It will supplement often whatever knowledge there be of local signs, with the indications of the instruments. Its careful use taken either with the furnished reports or even without them (if they chance to fail), will often enable the character of the coming weather on the coming day to be so judged as to determine what kind of work or undertaking it is wise to plan for or to omit. The case gives the local instrumental indications, and will frequently aid in making fair forecasts for the next day.

It is well to limit the forecasting to the attempt to tell only whether it will or will not *rain* on the next day. Days on which it does not rain at all, are rated "fair," though the sky may be covered with clouds. Days on which there is rain enough to injure crops in the harvesting, are rated "foul."

It must never be forgotten that the weather case is only to aid, sometimes, in making up one's mind as to what the weather of the next day will be. While it will often be very useful, there will be many instances in which everything will be left in doubt.

Location

The weather case should be hung or stand in a fair light, where it will be always shaded, preferably on the northern side or part of the house, where it will not be exposed to artificial heat, and where there will be a free circulation of the air. It will be easier to find good locations in summer than in winter. As the readings of the instruments are examined for their general indications only, the great care as to the location will not be so needed for general use as if the readings were for exact record. For particular uses, the case may be particularly sheltered.

To Use the Weather Case at Sunset

(1) Read the description: See that the mean barometer index is set to the mean barometer reading for the place and for the month.

(2) Set the rain wind segment (or arc) and the dry wind segment (or arc) at the proper places on the wind-disc circle for the place and month.

At sunset turn the "long barometer pointer" until it covers the "short barometer pointer." Note whether on the "main barometer scale" the long pointer is then at a reading *above* or *below* (greater or less than) the mean barometer reading for the place and for the month. Move the "sunset barometer index" until it points to the same reading on the "main barometer scale" with the "long barometer pointer."

Note the direction of the wind and set the wind-disc pointer.

Set the sunset-disc.

Set the dry- and wet-bulb thermometers.

Endeavour to apply the "indications" printed on the face of the case, to determine what is to be the character of the next day. Read these "indications" carefully, and see how many of the instruments or discs *agree* in showing one or another kind of weather as to be expected.

Study the character of the clouds. The scud cloud is one of the prominent signs of coming rain. Learn to apply the local signs of weather changes, the more the better.

Examine the case frequently during the day.

It can always be found whether the "pointer" is moving toward the right or left—that is, whether the barometer is rising or falling—by turning the long pointer, so as to cover exactly the black barometer pointer; if then, on next examination, the black pointer is found to have moved toward the right, the barometer is rising. If the black pointer has moved toward the left, the barometer is falling.

At sunset of the next day set the case again; note whether the barometer has risen since the "Sunset Barometer Index" was set at the last sunset, whether the wind is in the rain or the dry direction, and for how many hours it has been in either, approximately. Study and record the character of the sunset and what it foretells. Set the wet- and dry-bulb thermometer, and note from the "keepers" whether the thermometers are approaching or separating.

Endeavour to make a forecast whether it WILL or NOT rain for the ensuing day, as well as a more general forecast.

For instance, if with a "fair weather sunset" there is a "high and rising barometer," "winds in dry direction," and "thermometers separating," the chances for a fair day for the next ensuing are increased; four indications of pleasant weather coincide. If, with a "foul weather sunset," the barometer is falling" (the pointer moving toward the left), the winds are in the rain-wind direction, and "thermometers approaching," four indications of rainy or unpleasant weather coincide. So three indications may coincide, as, with "thermometers approaching" there may be "fair weather sunset"—barometer pointer moving toward the right or high barometer—wind steady in the dry direction. The indications may be divided. In such cases weight must be given the different indications as experience may show their correctness. The purpose of the case is to be one aid only in making up a forecast.

The greater the number of the "indications," as stated on the face of the case, which are found when the instrument is set, to coincide in indicating dry or clear weather, or rainy or stormy weather, the more likely the success of the forecast.

Continue this practice at sunset from day to day. Skill will be found to increase with the knowledge and the use of the instrument and the habit of close observation of local signs which such use makes necessary.

In instances where the printed synopses and indications are had regularly, or where official weather charts, bulletins, &c., can be consulted, the weather case must be used with careful study of those papers. Locate the areas of high and low barometer on the map, and in reference to any location, as nearly as is practicable from the descriptions or data. Areas of cloudiness, rain-areas, areas of unusual temperature, &c., may be similarly located. When any such areas are found to the westward of and at all near any place, it is rare that the effects of them fail to be shown at such place by weather conditions similar to those within the areas noticed, and in a short time, as of hours or days. As the movements of the

areas, easterly, have a certain regularity, it is soon learned to tell nearly *when* the effect of any area noticed as approaching will commence to be felt. The instrumental signs of the weather case will show the changes commencing, and it may be judged whether or when the weather conditions noticed in the approaching area are likely to prevail. Some elementary knowledge of meteorology is needed; but much can be done by a careful watching, solely. The instruments of the weather case will show the changes anticipated when they begin to be felt and before they have arrived in their full force.

If the area noticed has been large or small, with weather conditions decided or variable, it can, from these facts, be judged often if the "coming weather," of whatever kind it may be, will be steady for a day or for days, or more rapidly changing. The case makes practicable other and many studies.

ARE THE "ELEMENTS" ELEMENTARY?[1]

II.

IT would be a curious speculation were one to ask one's self what *is* the atomic weight of ozone? Is it 24? Is its atomic formula O1·5? or has oxygen the atomic weight of 32 and ozone of 48, and are the molecular weights 64 and 96 respectively? This can scarcely be, for the smallest amount of oxygen in two volumes of a gaseous compound of that element is certainly not 32, but 16 parts by weight. In fact *atoms* of allotropes scarcely appear to exist, the molecule appears to be the smallest amount of one of these substances that can exist either in, or out of combination. But can elements really exist in combination under various allotropic forms? We do not know. Weber thinks they can, Clarke thinks they cannot. The example of graphitic acid sometimes cited as proof of the existence in the combined form of allotropic carbon does not appear to me to *prove* either one view or the other. Graphite, may we not say, is an intermediate stage in the formation of graphitic acid from carbon? But it does not follow that the carbon in that acid is in a form different from that under which it exists, say in sugar. But it is exceedingly difficult, as yet, to attach a definite meaning to such a statement as "Carbon exists *under different forms* in this and in that compound."

The specific heats of allotropes vary. Weber has most carefully determined the specific heats of the modifications of carbon and boron. The numbers obtained at low temperatures are different, but when we come to those temperatures at which optical differences disappear, we find that differences in specific heats disappear also. At high temperatures there is but one specific heat for carbon and but one for boron; at low temperatures there are two or more specific heats for each. This seems to mean that at sufficiently high temperatures there is but one form of carbon and but one form of boron. As we do not know the atomic or molecular weights of the allotropic modifications of these elements, we can, it seems to me, draw no conclusions of any value concerning the atomic heats of these allotropes, and therefore the fact that the atomic heat of the elements is a constant number may be explained equally well on the hypothesis that the elements are all allotropes of one of themselves, or of an unknown substance, and on the hypothesis that the elements are essentially distinct forms of matter. It is well to bear in mind that, so far as our knowledge of allotropy goes—and it goes but a very little way—we have reason to believe that each allotrope has a different molecular, and therefore, probably, a different atomic weight, from every other allotrope of the same element; and, further, that we know that allotropes are at high temperatures resolved into one and the same form. Phosphorus has an abnormal vapour density: two volumes of the vapour of this body contain four (relative to hydrogen as two) atoms; red phosphorus (P_β) changes into common phosphorus (P_α) at comparatively low temperatures, therefore we do not know the vapour density of P_β. At a point not far from its boiling point, two volumes of the vapour of sulphur contain six atoms (if $S = 32$); at a higher temperature two volumes contain two atoms. We appear to have here a real gaseous allotrope. Is it analogous with ozone? Is it not therefore probable that the densities of P_α and P_β would be found to be different, supposing they were both obtained as vapours? But even P_α is abnormal. May it not be, then, that we have not as yet obtained normal phosphorus at all? That what we call phosphorus is an allotrope of the true phosphorus, viz., P_2? May it not be that at very high temperatures P_α splits up and yields true normal phosphorous vapour? Now let us briefly glance at isomers, or compounds having the same composition, but with different molecular weights. The mere fact that compounds of the same composition, but different molecular weights, exist, especially when taken in conjunction with the further fact that different compounds having the same composition and the *same* molecular weights also exist, renders the theory that the elements are really compound bodies not altogether improbable. So little has been done in the way of exact determinations of the specific heats, specific volumes, and other physical constants, of isomeric bodies, that I forbear from pressing the facts that are known into the argument, but content myself with saying that a more or less simple relation appears to exist between the physical and the chemical nature of the various isomers. The generally accepted theory of isomerism seeks to account for the facts by supposing that the atoms of isomers having equal molecular weights are differently arranged: another theory—to me it appears that the one theory is complementary of the other—supposes that the differences in the action of isomers are to be traced to differences in the amounts of "energy" possessed by these isomers (would it not be better to say, to differences in the relations between the potential and kinetic energy of isomers, and also perhaps to differences in total energy?); whichever theory is applied to isomers may be equally applied to the elements, on the assumption that these bodies are really compounds of one simple form of matter.

The positive evidence in favour of the theory of the non-elementary nature of the so-called elements is not very great. Yet, to say that the elements *are* truly elementary is, I am persuaded, a statement which is not justified by the facts which we possess. Either hypothesis may be adopted as a working hypothesis: the former, that the elements are *not* elementary, is, it seems to me, likely to lead to more discoveries, and to pave the way to more far-reaching generalisations than the latter.

But why should no one have succeeded in decomposing one of the so-called elements? In a sense we have succeeded. Ozone is an element, but it can be decomposed. Oxygen may, I think, be said to be a simpler form of matter than ozone. The introduction of the battery into chemistry led to the decomposition of potash and soda; the introduction of new engines of research may lead to the decomposition of some of those bodies, our conclusions regarding the elementary nature of which rests upon the same kind of evidence as did the conclusions regarding the elementary nature of potash and soda before the experiments of Sir Humphrey Davy. Analogy prompts us to ask, Is it not possible that what we cannot accomplish in our earthly laboratories may be actually brought about

[1] A paper read before the Owens College Chemical Society. Continued from p. 593.

in the great natural laboratories of the sun or stars? And facts recently observed by Lockyer give some countenance to those who would answer this question in the affirmative. The spectra of compounds are as a rule more complex than those of elements. The former bodies, speaking broadly, yield channelled or band spectra, the latter line spectra. The non-metallic elements, also, yield spectra which may be generally described as channelled or band spectra, while the spectra of the metals are more to be described as line spectra. Again, with increase of temperature band tend to change into line spectra; with increase of temperature compounds tend to be decomposed into their constituent elements. But the solar spectrum is a line spectrum, the spectra of certain stars—Sirius, &c.,—are line spectra, but simpler in their character than that of the sun; the hydrogen line is predominant in the Sirian spectrum. The spectra of certain other stars—*e.g.*, the red stars—are very complicated, and consist for the most part of bands and channelled spaces.

Putting these facts together, the hypothesis has suggested itself to Lockyer that the atmosphere of the red stars contains certain compounds and many non-metallic elements, that the atmosphere of the sun is characterised by the presence of metals, there the non-metals are decomposed into simpler forms, that those elementary bodies which are not found in the hotter part of the sun's atmosphere *are being* formed in the upper and cooler portions, but as they descend they are again dissociated, and lastly, that in the very hot stars our elements are for the most part resolved into simpler forms. Hydrogen, however, appears to exist there in the form in which it is known on this earth. This hypothesis is put forward tentatively by its author, and must only be accepted as a working hypothesis. It is most interesting to the chemist; in some of its bearings it also tends to throw light upon the physical conditions of the existence of stars and suns. Yet it is only an hypothesis, we must beware of accepting it as a dogma.

There is one point as bearing on Lockyer's hypothesis to which I should wish to direct attention. Non-metals show more variations in their spectra than are exhibited by the spectra of the metals. Metals yield, as a rule, only line spectra, non-metals channelled, then line spectra, as the temperature increases. Analogous with these changes in the spectra of non-metals is the well-known "plasticity" of these bodies. The instances of allotropy about which we have any accurate knowledge are instances among the non-metallic elements; probably, then, these bodies will be more readily decomposed than the metallic elements.

Putting together all that is known on the subject, the balance of probability appears to me to be in favour of the hypothesis that the elements are not really elementary. But if one is asked to put forward a positive hypothesis, not merely to favour a negative one, the task becomes much harder.

In a short, but exceedingly suggestive paper ("Speculative Ideas respecting the Constitution of Matter," *Phil. Mag.*, February, 1864), Graham tentatively put forward the hypothesis of original matter having a molecular or atomic structure, all the molecules being uniform in size and in shape, but not all possessed of the same amount of motion. In the differences in the motions of the parts of this original matter Graham sees the origin of all differences in the properties of our various elements. The gaseous molecules which we are accustomed to measure are not, says Graham, to be regarded as the ultimate molecules of the original matter, but as composed of a "group or system" of these. This hypothesis of Graham appears to me to be one of great merit. But if we start with one matter, whose molecules are of equal mass, may we not imagine these molecules originally possessed of equal amounts of motion? Having got these molecules, it is not, I think, beyond the powers of the scientific imagination to regard some of them as coming within the sphere of each others' action, and as coalescing to form new compound molecules, the mass of such new molecules being of course different from that of the original molecules. After such an encounter the new molecule will possess an amount of energy different from that possessed by the original molecules; hence it will exhibit new properties. The original matter has thus become differentiated; we have now more than a grained structure, the grains vary in mass, and in the amounts of energy which they possess. This process of evolution of higher and higher orders of molecules may proceed (may be now proceeding) until we arrive at those systems which are at present generally regarded by chemists as the molecules of distinct forms of matter, as the elementary bodies of to-day. These elementary bodies are again ready, under proper conditions, to form yet higher orders of molecules; these are our compounds, but these higher orders are less stable, under average conditions, than the lower (elementary) orders of molecules. If by any means a very large amount of energy be added to our elementary molecules they would tend to dissociate and to reform the simpler orders or groups from whence they have been derived. Such addition of energy appears to be given in the intensely hot atmosphere of the sun, where metallic bodies may seemingly remain in company with heated oxygen, yet unoxidised. If, however, a small amount of energy only be given to an element, then that element becomes ready to unite with another, or with others, to form a compound body. The bodies which we call elements would, on this hypothesis, be but intermediate stages in the evolution of complicated compounds from one original form of matter. At certain stages in this process points of comparative rest are reached; one of these points marks the existence of our so-called elements. Bodies which are elementary in our laboratories are compounds in the more energetic laboratories of the sun and hot stars. Many of our compounds, again, are elementary in the cold, listless atmosphere of the moon. Just as it is very difficult, if not impossible, to define a chemical compound, to say where the mere mechanical mixture or aggregation ends and the true chemical compound begins, so, in this view, would it be impossible to define a chemical element. Whether a substance is compound or elementary depends upon the point of time at which the investigation is made and upon the conditions of the environment. Graham has pointed out that the "colloidal state" seems to intervene between the liquid and crystalline states; the experiments of Faraday, of Caignard de la Tour, of Andrews, and more recently of Pictet and Cailletet, have taught us that between the gaseous and liquid states there is no hard line of demarcation; many facts in chemistry and in chemical physics appear to be explicable only on the supposition that the passage from mechanical mixture to chemical union is a gradual and continuous, not an abrupt and discontinuous one. Why, then, should not the passage from the one original element to the one final compound be also a gradual passage?

And as in animate nature we know that the (comparative) permanence of a species is in no way contradictory to the general law of gradual development, so in the history of molecular arrangements it may be that the present permanence of our so-called elements only marks a resting point in the slow but sure process of formation of more and more complicated compounds. The average conditions of our present surroundings may not allow of the existence of any less complicated molecular aggregations than those which we call elementary, just as they do not appear to allow of the existence of any extremely complicated aggregations of chemically united molecules.

There is another aspect of the question upon which one

word may be said. I think that I am not in error in saying that the minds of most persons are imbued, more or less deeply, with the idea that nature is ultimately very simple; that could we but grasp the great laws of nature we should find them extremely simple, although the results of their actions are so wonderfully complex. This belief appears to be deep-rooted in most minds, yet if we are to study nature aright we must, I am persuaded, set it aside. We must be content to take nature as she is, *i.e.*, we must do our best to amass facts, and from these we must draw the conclusions warranted by the facts. Now as our knowledge of nature extends do we find that she becomes to us more and more simple? Yes, and No. It has been now and again given to a gifted few to pierce through the maze of tangled facts and to espy the great principle which binds them into an harmonious whole. But even in the case of these great generalisations, exact experiment and observation frequently show that little details have been overlooked—that the great simple law is too simple—that there are discrepancies, *very small*, it is true, but still there they are, demanding an explanation, telling us that our law does not express the whole of Nature's facts. Nature appears to be truly infinite; and it is well to remember that, *we can never get sensibly nearer a knowledge of an infinity*.

This idea of the simplicity of nature is very apt to lead us to adopt the hypothesis of the non-elementary nature of the elements without sufficient evidence. The idea that all the elements are really compounds of one primary form of matter is a most fascinating idea, it *seems* to be so much in keeping with the simplicity of nature; it is so symmetrical, it surely *must* be true. This is just how the old alchemists reasoned; we must absolutely forbid these *à priori* conclusions to influence us as students of nature. The hypothesis of the compound nature of the elements, of the existence of but one, or even of a few primary forms of nature, fits in with the nebular hypothesis of the formation of the worlds, but have we facts to support it? If one can only come back to facts we need not fear to start what may appear to be wild and romantic theories.

The outcome of the whole matter is this:—we want more knowledge, our facts are few and vague; there is room for almost unlimited work. Ask Nature; trust her: be sceptical of your own interpretations of her answers. M. M. PATTISON MUIR

THE LATE SIR RICHARD GRIFFITH, BART.

WE have just laid to rest all that is mortal of the "Father of Irish Geology" in Mount Jerome Cemetery, at the ripe age of ninety-four years. Few public men in Ireland have done so much for the material advancement of their country. If "the age makes the man" the late Sir Richard Griffith was the man whom the age called forth to indicate the road to material improvement at a time when roads, railroads, drainage works, and similar agents were urgently required in this country. Griffith's geological knowledge was the basis of his power; and while few understood, or cared to understand, the principles by which his judgment was guided, Government and the public were always ready to put faith in their application. Amongst the useful works carried out under his direction were the roads which he constructed or improved in the counties of Cork, Kerry, and Limerick, during the time when the Marquis Wellesley was Lord-Lieutenant. Some of these roads are striking examples of engineering skill. I have recently travelled on one of them, namely, that which crosses the wild and rocky range between Kenmare and Glengarriff. Before this road was made the country was inaccessible and the haunt of Whiteboys; now no district in the British Isles is safer for the traveller, and, I may add, more full of bold and beautiful scenery. With reference to Griffith's services to the cause of Irish geology, it is unnecessary for me to say a word here, except in so far as regards the public department with which I have the honour to be connected. It is to this subject that I wish especially to direct the attention of the readers of NATURE, as I am anxious to pay a tribute to the remarkable acumen which Griffith exhibited in determining the age of the various formations which are to be found in this country, as exemplified in at least one special instance.

It is well known that there is one point in the geological structure of the south-west of Ireland on which there has been a difference of opinion between the Government geological surveyors and Sir R. Griffith; I refer to the age of that great group of rocks which occupies the mountainous districts of the Dingle promontory, and those of Killarney, the Reeks, and Glengarriff. These were called by the late Prof. Jukes "The Dingle Beds," and they consist of a series of purple slates traversed by cleavage planes and massive green grits, and thrown into numerous grand flexures. They are of great but unknown thickness, as in the Dingle promontory they are overlaid unconformably by the beds of the Old Red Sandstone. In the Dingle promontory these beds are seen in contact with fossiliferous beds of recognised Upper Silurian age, and the whole series had been referred by Griffith to the "Silurian" formation, as may be seen by reference to his geological map of Ireland (edit. 1855). In a similar manner the mountainous regions abovenamed, and lying to the south of Dingle Bay, were mapped and coloured as "Silurian," and were separated off from the Old Red Sandstone throughout the counties of Cork, Kerry, and Waterford.

The views thus held and published by Griffith with regard to the geological age of the rocks forming the south-western highlands were not upheld by the officers of the Geological Survey, who, we may be sure, spared no pains to come to some clear decision on the question. On the maps of the Survey the mountains of Kerry and Cork are coloured "Old Red Sandstone," and "the Dingle Beds," with a distinct colouring, are placed in a position intermediate between the Old Red Sandstone and that of the Upper Silurian. Prof. Jukes, in the "Explanations" to accompany the maps of the Survey, has fully entered into the reasons which induced him and his able colleagues to arrive at this decision. Certain apparent obscurities in the sections of the Dingle district and those of the neighbouring regions prevented them accepting Griffiths' views, and the whole matter was left an open question, subject to further investigation.

Under these circumstances—the time being favourable—I received the sanction of the Director-General to make a preliminary examination of the sections at Dingle and in the districts of Killarney, Kenmare, and Glengariff—with a view (if possible) of coming to some decision on a question which has been confessedly left in an unsatisfactory position. In this tour I was accompanied by Mr. J. O'Kelly and Mr. A. McHenry, officers of the Survey—and we have returned from it fully satisfied in our own minds of the correctness of Sir R. Griffith's views regarding the age of the beds of the Dingle, Killarney, and Glengarriff Ranges. To our minds the evidence is clear and satisfactory that these beds are really of Upper Silurian age, as maintained by Griffith. Into this evidence I cannot enter here, but hope to do so at some length in another place. It was with great gratification that some days since I addressed a letter from Eccles' Hotel, Glengarriff, to Sir R. Griffith, announcing the result of our investigations. I little knew that at that moment the spirit of our venerable friend had passed away! Few men were less dogmatic in maintaining their conclusions than Griffith. If others differed from him he remitted the matter to the arbitrament of time, satisfied that if he was in the right time would show it. In *this* case it is only justice to his

memory to bear testimony to the soundness of his judgment. EDWARD HULL

Geological Survey Office, Dublin, September 27

ROBERT HARKNESS, F.R.S.

ANOTHER of the captains in the phalanx of British geologists has dropped from the ranks. Robert Harkness died suddenly in Dublin on Saturday last. He had been ailing for some time, and the disease from which he suffered—an affection of the heart—had gained ground so much this year that he lately felt himself compelled to resign the chair of geology at Cork. It was the expectation of his friends that, released from duties which he had so long conscientiously performed, he might yet enjoy some years of comparative health in the quiet retirement of his Cumberland home, to which he used to return with such pleasure every summer. But this was not to be. He has fallen just as he had himself brought the public labours of his life to a close.

It is now some five-and-thirty years since the name of this able geologist first appeared as a writer on his favourite science. During this long period he had explored, on foot, the geology of large districts in the north of England, in Scotland, and in various parts of Ireland. The reports of the British Association and the *Quarterly Journal* of the Geological Society bear witness to his industry and to the painstaking minuteness of his method of investigation. To him we owe our earliest exact information regarding the correlatives of the reptiliferous sandstones of Dumfriesshire and Cumberland. It was his patient labours continued year after year over ground most difficult to unravel, that led the way to the working out of the structure of the silurian uplands of the south of Scotland. To his research, too, is due the identification of the metamorphic rocks of the north-west of Ireland with those of the west of Scotland. To the elucidation of every one of the palæozoic systems of deposits he contributed something of value.

But important as was his scientific work, it had not a wider and more hearty recognition among his brother geologists than his own admirable qualities of head and heart. Who that has been privileged with his friendship will not cherish the memory of his earnestness over even the driest of details, his quiet enthusiasm, his generous admiration for the work of others, his unfailing cheerfulness? Who will forget that beaming ruddy face, never absent from the platform of Section C at the British Association meetings, always ready to rise among the speakers there and to reappear at the festive gatherings in the evening? There have been men who have graven their names more deeply on the registers of scientific thought and progress, but there have been few whose sunny nature has more endeared them in the recollection of their friends than Robert Harkness. A. G.

MANGANESE NODULES IN LOCH FYNE

ON September 21, this year, I anchored the steam yacht *Mallard* near the mouth of Loch Fyne, in 104 fathoms, for the purpose of making physical and chemical observations on the water of this, the deepest part of the Firth of Clyde. When the anchor was got up a large mass of clay and shells was found sticking to one of the flukes. It was gently dried, and on examining it I observed a number of nodular concretions, which, on being freed from the surrounding clay, presented a finely mammillated black surface, were easily cut with a knife, giving a brownish-black powder, which liberated chlorine from strong hydrochloric acid, and possessed all the properties of peroxide of manganese; in short, they were identical with the manganese nodules which we found in the *Challenger* to form so important a constituent of the sea-bottom in the greatest depths.

One half of the dried mud was carefully broken up and searched through, the nodules being collected by themselves and also the shells. It was thus separated into three portions, which were weighed, with the following results:—

Manganese nodules ...	142·7 grammes. ...	30 per cent.
Shells	35·0 ,, ...	7·5 ,,
Sandy clay	289·0 ,, ...	62·5 ,,
Total	466·7	100·0

The manganese nodules, therefore, made up thirty per cent. of the weight of the mud. Compared with those frequently met with on board the *Challenger*, the nodules were small. In the sample examined there were eighty-three nodules weighing 142·7 grammes, hence the average weight was 1·7 grammes. Their volume was found to be 58 c.c., so that the average volume was 0·7 c.c., and the specific gravity 2·46. Their form was roughly spherical, the largest, which was somewhat elongated, measured $13 \times 9 \times 6$ millimetres, the average diameter of them all being 11·4 millimetres.

Of the eighty-three nodules so obtained I have split twenty-two. When subjected to this treatment they are found to differ in constitution from the majority of those obtained on board the *Challenger*. Although they had not been exposed to any heat they were hard and sandy to the knife, and when treated with strong hydrochloric acid, they left a large amount of mineral (chiefly quartz) sand. This difference, however, is explained by the different kind of bottom from which they were obtained. In dissolving up nodules which had come from "red clay" in 2,500 or 3,000 fathoms I always found the same mineral sand left as on treating the clay in the same way. But the amount of sand was always quite insignificant, as compared with the clay; hence the nodules were easily cut with the knife. They, however, got harder on keeping. In Loch Fyne the bulk of the mud consists of quartz sand, giving the nodules the appearance of sandstone, whose binding material is made up to a great extent of peroxide of manganese, and hence the gritty feeling to the edge of the knife.

Where a hard nucleus has been found it has always been a piece of rock from the neighbouring shore, but in most instances (in sixteen out of twenty-two examined) the ordinary arrangement has been reversed, the nodule consisting of a soft rich nucleus of peroxide of manganese, surrounded by a black sandy rind, the whole enveloped in the characteristically mammillated black skin.

I hope very shortly to be able to report more fully on them; in the meantime, I have only been able to verify their nature by finding abundance of a higher oxide of manganese, easily recognisable quantities of cobalt, and the presence of water, which, on being expelled by heat, has an alkaline reaction and an empyreumatic odour, properties in which they agree with those which I had occasion to test on board the *Challenger*.

Their position in the mud, with dead shells above, below, and on all sides of them, will, when carefully studied, no doubt throw much light on their age and method of formation. I have observed two nodules firmly attached to the interior of shells, one having evidently been directed in its growth by the shape of the shell.

In endeavouring to procure a further supply I dropped anchor in about the same depth, but about a hundred yards further down the loch, and I obtained about the same amount of mud, but it contained very much more shell and no nodules. Also in Kilbrennan Sound, between Arran and Cantyre, in a depth of eighty-five fathoms, there was much shell and pebble, but no nodules. So far, therefore, this occurrence appears to be very local.

J. Y. BUCHANAN

STATE AID TO SCIENCE

UNDER this title the last number of the *Lancet* has the following :—

It was for a long time the fashion with zealous workers in the field of science to protest that the cause of discovery would not be advantaged by State patronage or State aid. The more thoughtful inclined to the belief that the patronage would be more mischievous than the pecuniary assistance was helpful. For some years past this persuasion has been losing ground, and, whether scientists are becoming more worldly or less exclusive in their views, it is abundantly evident that the reverse of a feeling of unwillingness to accept aid from the State prevails. It will doubtless be contended that the way in which help has been placed at the disposal of explorers and investigators so completely removes all difficulties, that it would be not less ungracious than impolitic to refuse the proffered assistance. The labourer chooses his own form of enterprise, or applies for aid in the course of an inquiry instituted at his own wish, that he has simply to satisfy a committee of fellow-workers as to the object of his pursuit or the nature of his researches, and, upon their recommendation, the necessary funds are forthcoming, without the least semblance of dictation or interference. The explanation is obviously satisfactory, but the fact remains, the objections which many of the older and more successful discoverers urged against seeking or accepting the assistance of the State in their investigations have been discarded, and the only grievance felt by contemporary inquirers relates to what they conceive to be the paucity of the grant and its wrong distribution, for which last fault, if fault there be, the governing bodies of the principal scientific societies are mainly responsible. We offer no present opinion as to the comparative merits of the old and new view of the State aid question, and we do not propose to discuss the complaints arising out of the system of administration extant; it is for the more pressing issue, whether a permanent provision should not be made for the support of men who live by investigation rather than teaching, we now ask a few minutes' attention.

It must be conceded by all who have any acquaintance with the subject, that not only the pioneers, but, in a practical sense, the advanced workers in science must necessarily be debarred from the ordinary rewards of their profession. If it be difficult to practise and preach, it is incomparably more embarrassing to study and teach. In short, the explorers and investigators in any department of work cannot live by communicating the knowledge they accumulate. The business of utilising the store of information amassed by the labourers in the advanced field must be performed by men who are not themselves engrossed with research. The enterprise of discovery cannot be delayed while the explorers strive to popularise their acquisitions, nor are the faculties which prove most useful in the field of inquiry especially well adapted for successfully imparting the knowledge obtained. The functions of the scholar and the schoolmaster, the collector and distributor, are essentially different; we might go further and affirm that they are scarcely compatible. It follows, therefore, that the two classes of workers must always exist. Some must make knowledge and live by that form of labour, while others distribute or apply it to general uses. It seems to follow, without the need of argument, that by some expedient the means of self-support must be placed within reach of those who are not in a position to render their produce marketable. This necessity has been long recognised, and with a view to meet the case, College fellowships and snug sinecures in the Church and at Law have been preserved for the shelter and support of those who required scholarly leisure for the pursuit of inquiries. The spirit of the age is, however, eminently utilitarian and strongly opposed to sinecures; and, as a matter of fact, the system was manifestly open to abuses. The medical profession has never largely enjoyed these advantages, although the discoveries made by its members are equal, if they do not surpass, those of any other branch of labour in science. The time has come when the whole question needs to be discussed from a new standpoint, and in a more practical fashion than hitherto. We venture to suggest that it should not be left in the hands of interested persons who cannot speak freely on the topic, but considered by the profession as a body. The points to be adjudicated are: first, has medicine its full and fair share of State aid? and secondly, has not the time arrived when some formal provision should be made for the support of men who devote their lives to inquiry and cannot reasonably or expediently be expected to practise or teach? In the old days much of the hardest work in science was done by Churchmen of the various orders who were supported by the ecclesiastical institutions of the country; now the labour of research is performed by laymen, and they must live.

THE TOURNAMENT OF INCUBATORS

IN a recent number we referred to the hydro-incubator invented by Mr. Christy. This incubator, along with a number of others, has been subjected to a comparative trial at the Hemel Hempstead Waterworks. An account of this competition appears in the *Live Stock Journal*. It commenced 6 A.M. September 5, and concluded on September 26, at 12 o'clock noon. The object of the committee who tested the incubation was—

(1) To ascertain whether incubators were of any practical value to the public generally; and

(2) If proved to be of value, to decide which was the best incubator for the ordinary purchaser to select.

That the person to whose management the incubators were entrusted should be unskilled and inexperienced in their use, was one of the conditions specially insisted on by the exhibitors. This was considered the best means of proving which incubator was of the simplest construction and could be worked most successfully without any previous apprenticeship. A large room in the Waterworks building was secured, where steam, hot water, or gas, could be employed, and where perfect privacy and quiet could be secured. Exhibitors were requested to send their incubators with full and clear instructions as to their method of working.

The eggs, which should be laid on Wednesday, September 4, had been bespoken some time before at several farmhouses in the neighbourhood, and these having been collected during the afternoon of that day, were brought to the Waterworks, and thoroughly intermixed by the members of the committee. Each egg was then marked with the word "*Couveuse*," by a stamp made at Brighton expressly for the occasion. By six o'clock on the morning of Thursday, September 5, the eggs had all been placed in the incubators by the members of the committee, the machines having been fully prepared for their reception. The incubators were then intrusted to the engineer, Mr. Twigg, with strict injunctions to follow implicitly the instructions of the exhibitors, and to admit no one without a written order from the committee to the room, which was to be kept locked, especially the exhibitors themselves or their agents. The following are the statistics of the competition itself, which were attached to the incubators as soon as possible after mid-day on September 26:—

No. 1.—VOITELLIER: Hydro-Incubator.

Of fifty eggs placed in incubator none were hatched.

This machine, from its simplicity and the ease with which the thermometer could be consulted, was quite a favourite with the engineer, who was most sanguine as to

its results, and much disappointed at its failure. On subsequent examination no chickens were found in the eggs.

No. 2.—CHRISTY: Hydro-Incubator.

Eggs placed in incubator		50
Found fertile after testing	45	
Unfertile	5	
Broken during competition	0	
Hatched by 12 noon, September 26 ...	34	
Not hatched 11	11	
Percentage of eggs hatched		75·55

Three more chickens were hatched alive after the competition had closed. The other eggs, on being examined, were all found to have living chickens in them. The prize of 25*l*. was awarded to this incubator.

No. 3.—CHRISTY: Hydro-Incubator.

Eggs placed in incubator		50
Found fertile	45	
Unfertile	5	
Broken during competition	1	
Hatched by 12 noon, September 26 ...	20	
Not hatched	24	
Percentage of eggs hatched		44·44

Two chickens were hatched alive after the competition was ended. Of the remaining eggs ten were found to have living chickens in them.

No. 4.—BOYLE: Heated by lamp.

Eggs placed in incubator		48
Found fertile	40	
Unfertile	3	
Broken during competition	2	
Hatched by noon, September 26 ...	11	
Not hatched	27	
Percentage of eggs hatched		27·55

On examining the eggs, Saturday, September 28, four chickens were found ready to break the shell. This incubator worked with great regularity, and deserves much commendation.

No. 5.—BOYLE: Heated by gas.

Eggs placed in incubator		52
Found fertile after testing	42	
Unfertile	10	
Broken during competition	26	
Hatched by 12 o'clock noon, Sept. 26...	0	
Not hatched	16	
Percentage of eggs hatched		0

The egg rests in this machine are spiral wire springs The egg drawer did not fit well, and is certainly capable of improvement. Full and very clear instructions should always accompany this incubator. Its want of success must not be attributed altogether to the inexperience of the attendant.

No. 6.—PENMAN'S (worked by lamp): Exhibited by Messrs. E. T. Brown and Son, Newcastle-on-Tyne.

By this no eggs were hatched, but twenty dead chickens were found in the eggs on September 28, having been dead apparently several days. The lamp in this incubator worked very irregularly, needing constant attention by day and night.

No. 7.—PENMAN'S (worked by gas).

By this also no eggs were hatched, but on examining the eggs at 6 P.M. on Saturday evening, Sept. 28, thirty-four chickens were found to be alive in them, two having been hatched out on the same morning alive. The source of heat—viz., gas—had been turned off at 8 P.M. on the Friday night previous, and the drawer had been opened and shut constantly after the exhibition was opened at noon on Thursday. The irregularity of heat from the gas was doubtless the cause of failure in this instance, the pressure being very unequal.

The committee subjoin to this report a register of the temperature maintained in the drawer of each incubator, together with that of the water drawn off from the boilers in the case of the hydro-incubators. The chickens hatched are doing well, some under them, some in artificial mothers.

Such are the facts of this interesting trial, and they seem to us to prove not only that artificial incubation is possible, but that by Mr. Christy's machine, if not with some of the others, it might become a remunerative business, and add materially to the sources of our food supplies.

NOTES

BY the kindness of Gen. Myer, the distinguished head of the U.S. Army Signal Service, we are enabled this week to give the official description of the weather case, the distribution of which among the 27,000 rural post-offices in the United States has just commenced. It is for use in those parts of the country where the daily weather indications cannot reach in time to facilitate agricultural operations, and its issue has been forced upon the Government because the American farmers are wise enough to see that for them, as well as for sailors, to be forewarned is to be forearmed. In a few centuries we may expect to have something of the same kind here.

M. BOUILLAUD, the once celebrated medical practitioner, who is a member of the Paris Academy of Sciences, assailed M. du Moncel in the sitting of September 30, and asserted that the phonograph and microphone experiments must be the work of ventriloquists. This fit of incredulity was occasioned by the recital of experiments made with the singing conductors. M. du Moncel asked for a commission of investigation to be appointed, although such accusations are not deserving of any notice, and have, indeed, raised universal ridicule. But the regulations of the Academy forbid any commission to be appointed to pronounce on the works or communications of members. Another curious scene took place at the sitting of last Monday. M. du Moncel presented to his colleagues, the "condensateur chantant," which had been exhibited on the previous Saturday. He retired to the room of the Académie Française, in company with M. Faye, closed the door and sang. His voice was heard coming from a number of sheets of paper, in which six sheets of tinfoil had been inserted, and connected with the wires of an induction coil. M. Bouillaud was obliged to retreat from the position he had taken at the sitting of September 30. He made no allusion to the accusation of ventriloquism, but read a long quotation from Descartes, to show that "even if a speaking machine had been constructed, it could by no means be considered as a thinking machine." He said that speaking was not only a mechanical action, but also an intellectual work, so that neither the phonograph nor the singing condenser could be regarded by any means as really speaking! The whole assembly, in spite of its usual gravity, burst into roars of laughter. M. Milne-Edwards, who spoke at the previous sititng, said with much propriety, he should not have answered M. Bouillaud if he had understood such was his issue. Unfortunately he had understood, as everybody in the assembly did, that M. Bouillaud questioned the honesty of the experimenter. At the end of the sitting M. du Moncel performed all the principal experiments of the phonograph.

SOME remarkable experiments in Electric Telephony were shown by Prof. Barrett in a lecture at the Midland Institute a

few days ago. By means of Edison's carbon telephone, which promises to be the telephone of the future, the lecture was electrically transmitted to the Arts Club in an adjoining street, though the transmitting instrument was several feet from the speaker; conversely, an assistant, speaking near to the distant carbon transmitter, was heard in a dozen different receiving magneto-telephones distributed through the lecture Hall. Further, by employing a single "Phelps" telephone as receiver, and using a paper cone as the mouth-piece of the telephone, 300 or 400 people in the neighbourhood of the instrument were able to hear distinctly sentences and songs given to the distant carbon telephone. And finally, by the same means, the entire audience of some 1,500 people heard single words, such as Bravo! Halloa! &c., spoken to the far telephone. Other experiments, of a more crucial character, demonstrated that this new telephone of Edison's will probably place electric-telephony on an entirely new and more practical basis. Prof. Barrett also showed Mr. Edison's tasimeter, an adaptation of the principle of the carbon telephone, the instrument having been kindly sent over by Mr. Edison for this lecture. The extraordinary delicacy of the tasimeter to heat radiation was shown to the audience by the heat radiated from the face throwing the beam of light reflected from a galvanometer completely off a ten-foot scale. The megaphone and several other of Mr. Edison's recent inventions were also successfully shown in this lecture.

NEWS of Prof. Nordenskjöld's North-East Passage Expedition has reached Stockholm. It left the north coast of Norway on July 25, reached Jugor Straits on the 30th; steamed on August 1, and arrived at the mouth of the Yenissei on the 6th. It was intended to start afresh on August 10. The Kara Sea was nearly free of ice. A little scattered drift ice near White Island was the only ice met with during the whole voyage. The expedition has thus a good prospect of success.

THE *Times* correspondent writes from Naples, September 29, that for the past two or three days, according to Prof. Palmieri's report, the activity of the mountain had much diminished, and the seismic instruments had been quieter. At the time of the new moon there was an increase of activity, as is always the case, and it will be witnessed, no doubt, at the time of full moon; but the mountain pursues its regular course, except at these seasons, and some little time must elapse before what the world calls an eruption will occur. Of what character it will be it is impossible to say precisely, but appearances indicate that it will be a lava eruption—presenting, indeed, a most brilliant spectacle, but unaccompanied by those horrors which marked the eruptions of 1854, 1861, and 1872; but, as Prof. Palmieri observes, it is impossible to say how it will terminate. A *Daily News* correspondent sends an interesting account of a visit he has paid to the crater of Vesuvius, into which he descended, and tells what he saw:—The actual crater is placed almost in an amphitheatre, three-fourths of which are inclosed, while one-fourth is open. The inclosing walls rise above the bed of the crater from 250 or more feet in some parts, apparently composed of sulphur. The diameter, judging by the eye, from one side to the other, is about 300 yards, and the whole of this area is filled with lava on fire, but crusted on the surface with a skin some inches deep of lava that has been chilled. "Looking between the cracks or down the 'crevasses,' the glowing fires a few inches below our feet, and in the blocks whereon we were standing, were seen. The ten months' activity has enabled the volcano to raise a cone almost in the centre of the crater at least a hundred feet in height, very wide at the base, converging to the summit like a sugar-loaf, but with the summit of the loaf removed. With a pulsation as regular and as marked as that of the piston of a steam-engine in full motion, did the huge mountain carry on its work, so that now we were able clearly to understand what was meant by 'every pulsation of the volcano being duly registered at the observatory.' Clouds of smoke and fumes were issuing from the summit of the cone—now densely dark, as if a fresh supply of coal had been heaped on the fire; then intensely light, as if the engine were blowing off its steam; then most beautifully and delicately tinted with the tenderest rose-pink, as if an artist were testing how best to combine the loveliest tints of his art; then a pale salmon, a little while, and then as if five thousand torpedoes were simultaneously exploded. The huge mountain seemed to heave, and forth from its mouth issued immense quantities of molten lava, shot scores of feet high up into the air—apparently at the mouth all in one body, but there separating into millions of pieces, great and small, all glowing with the most intense red heat that can possibly be seen. Each piece as it ascended into the air was separate; no piece was partly red and partly black, but was on fire and at red-heat throughout; mostly the lava emitted fell back again into the bosom of the heaving mass, but with every emission quantities, large or small, fell on the outside of the mouth, and thus we saw readily how the cone had gradually but continuously increased in size and height. Every now and then a huge mass would drop outside, and then would be heard an immense crash, followed by vast quantities of lava rolling down the sides of the cone. As we stood watching, at intervals there seemed to be the firing of 10,000 guns of mightier calibre than Krupp's, and we soon found that this was the precursor of a grand display. Up rose, possibly 100 feet above the cone, an immense mass spreading in the shape of a lady's fan, and presenting one of the most magnificent sights the eye of man can ever see. And this upheaval was not a thing for which we had to wait till our patience was exhausted, and to wonder if it would be repeated or not, but was continuous and incessant, and almost seemed as if every renewed expulsion were grander than its precursor, or as indicating a trial of actual strength prior to the great event proposed to be completed."

THE foundation-stone of the proposed railway bridge across the Firth of Forth was laid last week.

LAST March a microscopical society was formed in Highbury under the presidency of Dr. Alabone. The numbers have steadily increased, and the society appears to have all the elements for a career of great prosperity. The opening *soirée* for the winter session will be held at Harecourt Hall, St. Paul's Road, commencing at 7.30 p.m. to-night.

MANY valuable papers were read at the meeting of the Sanitary Institute at Stafford last week, and if Government and the public are ignorant of the laws of public health and the best methods of carrying these into practice, it is from no want of enlightenment. The great want at present seems to be organisation and an efficient central authority, and we trust the practical and vigorous address of Sir Henry Cole on Sanitary Co-operation will meet with attention in the proper quarters, and lead to more systematic and efficient action than has hitherto existed. In an able paper Dr. Richardson advocated the appointment of a Minister of Health.

MESSRS. HARDWICKE AND BOGUE announce the following works for publication:—"A Manual of the Infusoria, comprising a Descriptive Account of all known Flagellate, Ciliate, and Pentaculiferous Protozoa," by W. Saville Kent, F.L.S.; "The Herefordshire Pomona," containing Coloured Figures and Descriptions of the most esteemed kinds of Apples and Pears, edited by Robert Hogg, LL.D., F.L.S., Part I., illustrated with coloured figures and woodcuts; "Clavis Synoptica Hymenomycetum Europæorum, conjunctis studiis scripserunt M. C. Cooke, A.L.S., et L. Quelet, M.D., O.A., Inst. et Sorb. laur.;

"The Sphagnaceæ, or Peat Mosses of Europe and North America," by R. Braithwaite, M.D., F.L.S., &c., illustrated with 29 plates; "Pollen," by M. P. Edgeworth, F.L.S. F.R.S., second edition, revised and corrected, illustrated with 438 figures; "The Ferns of North America," by Prof. D. C. Eaton, of Yale College, illustrated with numerous coloured plates by James H. Emerton, to be completed in 20 parts, published at intervals of about two months; "Flowers, their Origin, Shapes, Perfumes, and Colours," by J. E. Taylor, F.L.S., F.G.S., second edition; "Health Primers," edited by J. Langdon Down, M.D., F.R.C.P., Henry Power, M.B., F.R.C.S.; J. Mortimer-Granville, M.D., F.G.S., F.S.S.; and John Tweedy, F.R.C.S. Under this title will be issued a series of shilling primers on subjects connected with the preservation of health, written and edited by eminent medical authorities. The following volumes will be issued in October:—"Premature Death, its Promotion and Prevention;" "Alcohol, its Use and Abuse;" "Personal Appearances in Health and Disease (illustrated);" "Exercise and Training" (illustrated); "The House and its Surroundings;" "The Skin and its Troubles" (illustrated); "Baths and Bathing." Others will follow at short intervals.

The national *fête* for the distribution of the Paris Exhibition awards will take place, as stated, on October 22. The whole of the Versailles Park will be lighted by electricity.

In connection with the meeting of the Library Association last week at Oxford, we would recommend to our readers' attention a most interesting and really amusing little *brochure* by Mr. H. B. Wheatley, entitled "What is an Index? A few Notes on Indexes and Indexers." Mr. Wheatley gives many amusing instances of how not to do it, and his pamphlet will be found useful not only to indexers, but to all who in any way have to do with the arrangement of written or printed matter. It is published by Sotheran and Co. The Library Association has already assumed vigorous proportions, and in spite of its much talk seems likely to do real service to existing libraries and to the promotion of new ones.

The great work of connecting the triangulation of Algeria with the geodetic net-work of Europe, through Spain, is progressing favourably. The Spanish staff officers under General Ibanez have established their post on Sierra Nevada and Mount Tetica, and the French near Nemours, and Ben Sabra, near Oran. M. Perrier, member of the Bureau des Longitudes, and director of the French Survey, will very shortly proceed to Algiers to take the last readings from the French side.

Of all the accidents to which submerged submarine cables are liable, one would suppose that that by fire would be the very last that would occur. Nevertheless, such an accident has happened to the Forth cable belonging to the Post Office. Lately all four wires were found earthy. The fault showed itself by test to be close to the shore. It was found below high-water mark at the foot of the cliff. Some boys during low water had been making a fire with the shavings and rubbish found on the beach, immediately over the cable, melting the compound and gutta percha of the core, and leaving the copper wires bare and in contact with the outside sheathing.

The municipality of Prague, advised by the Hygienic Council of that city, have just issued an edict prohibiting ladies from wearing dresses with long trains in the public streets, on account of the dust which the appendices raise being detrimental to public health. The municipality of Leipzig published a similar edict some time ago. These measures are easily explained by the habit assumed by many representatives of the fair sex of letting their trains drag through dust (and worse) for the sake of producing an effect which we presume milliners consider important from the point of view of sexual selection.

The Meteorological Central Office of Vienna reports upon an aurora borealis of immense extent on September 25. It appears that the phenomenon was visible for several nights in the whole of Scandinavia and Northern Russia. It covered the larger portion of the northern sky, and appeared in a yellowish red light, with frequent undulations of bright and intensely yellow rays.

We are glad to see that Prof. Geikie has added to the usefulness of his "Elementary Lessons in Physical Geography" by preparing a series of questions. These have recently been issued by Macmillan and Co.

The Paris *Temps* publishes daily the charts of the Central Bureau of French Meteorology. The experiment was tried by the *Opinion Nationale* two years ago, but was discontinued.

Prof. Lebour has prepared a convenient and complete catalogue of the Hutton collection of fossil plants, which are specially valuable as illustrating the carboniferous flora of some of the horizon in the Newcastle coal-field. The system followed is, with few exceptions, that of Schimper. The catalogue has been drawn up by order of the Council of the North of England Institute of Mining and Mechanical Engineers.

The *Cologne Gazette* announces that on Saturday night two slight shocks of earthquakes were remarked at Buir and in the surrounding district. The first occurred about 10 o'clock, and the second about an hour later. There was a slight shock of earthquake at Parma during the night of the 2nd inst.

The Annual Exhibition of the Photographic Society was opened yesterday.

There will be a meeting of anthropologists combined with an anthropological exhibition at Moscow during the summer of 1879.

The appearance of phylloxera in some vineyards near Bonn, on the Rhine, has been officially announced.

"Tables for Use in the Verification of Standards of Weight and Measure," by Dr. O. J. Broch, Standards Commission, Christiania, is the title of a valuable paper recently translated under the directions of the Standards Department, Board of Trade. It embraces tables of specific gravity, coefficients of expansion, elastic force of aqueous vapour, and the weight of water.

Mr. L. S. Benson, New York, of π notoriety, has submitted to English mathematicians his *demonstration* (this time in ink) of a *discrepancy* between the analytical and geometrical proofs of a property of the parabola, viz., that the area of any segment is exactly two-thirds of the rectangle on abscissa and ordinate.

The Dutch Government, encouraged by the excellent results obtained, in a commercial point of view, through the construction of the Y-Muiden Canal, which connects Amsterdam directly with the German Ocean, has now the intention to construct a similar canal to connect Amsterdam with Gorinchem, and to render the Waal and the Rhine navigable for sea-going vessels, so that even larger vessels could in future sail as far as Arnheim, and s'Hertogenbosch. Of course Rotterdam, Dortrecht, Moordijk, and Flushing would also benefit by the completion of the intended new works.

The New York *Daily Graphic* furnishes some particulars of interest respecting the Nez Percés, a tribe of Indians, the greater portion of which was captured by the United States' troops about a year ago and confined in an encampment near Fort Leavenworth, on the Missouri. Their chief, it appears, carries in his hand a looking-glass which "is used to direct military manœuvres in battle by means of reflected rays of light. Their various significations, however, have never yet been found out by the white man . . . . The orders are apparently

conveyed to distant parts of the field by a system somewhat similar to the dashes and dots of the Morse telegraphic code." The Nez Percés are described as a particularly fine race and well behaved. Their women are very industrious, and when not engaged in carrying wood and water, &c., "are generally hard at work in the manufacture of beaded mocassins, gauntlets, and Indian doll babies . . . The little boys, too, reap quite a harvest by displaying their skill with the bow and arrow." One of the most curious institutions of the tribe is a primitive description of Turkish bath. "The Missouri River runs close by their encampment, and on the bank of the river they have built what has the appearance of a gigantic ant-hill; in shape it is similar to a small Esquimaux hut, about six feet in diameter and two or three feet high. There is an aperture on one side just large enough for a man to get through, and in the interior there is just sufficient room for him to lie in a cramped position. They first build a fire outside in which they heat limestones until almost red-hot. They then shovel them into the hut and pour water on them so as to produce a dense vapour, after which they quickly rake the stones on, crawl in through the entrance hole which they cover up with a blanket, and lie there until the perspiration streams from every pore, when they come outside and plunge into the Missouri River and swim to the nearest sand-bank."

THE additions to the Zoological Society's Gardens during the past week include a Mona Monkey (*Cercopithecus mona*) from West Africa, presented by the Rev. W. N. Ripley; a Macaque Monkey (*Macacus cynomolgus*) from India, presented by the Rev. E. L. Marrett; a Cape Zorilla (*Ictonyx zorilla*) from West Africa, presented by Mr. Calman; a Laughing Kingfisher (*Dacelo gigantea*) from Australia, presented by Mr. Delves L. Broughton; a Red-beaked Weaver-bird (*Quelea sanguinirostris*) from West Africa, presented by Mr. W. H. Simmonds; a Passerine Owl (*Glaucidium passerinum*), European, presented by Miss Turner; a Sumatran Rhinoceros (*Rhinoceros sumatrensis*) from Malacca, an Anubis Baboon (*Cynocephalus anubis*), a Macaque Monkey (*Macacus cynomolgus*), a Bonnet Monkey (*Macacus radiatus*) from India, a Kinkajou (*Cercoleptes caudivolvulus*) from South America, deposited; a Chinchilla (*Chinchilla lanigera*), born in the Gardens.

CYON'S RESEARCHES ON THE EAR

I.

THIS able and elaborate thesis, presented by Dr. de Cyon to the Medical Faculty of Paris, contains a further contribution of facts and speculations in reference to the function of the semicircular canals of the internal ear, a subject upon which, as Professor of Physiology in St. Petersburg, he had previously published an important and interesting paper.

As a knowledge of the form and position of these organs is absolutely necessary to enable the reader to follow a discussion of the theories as to their use, we shall preface this notice of Dr. de Cyon's thesis with a short anatomical statement.

The system of semicircular canals, which exists in the internal ear of all vertebrates, while differing greatly in size in different animals, is so nearly the same in general arrangement, that a description of it as found in man will be sufficient for our present purpose.

These organs are lodged in a bony cavity continuous with the cochlea which contains the organ of hearing. The vestibule is an irregular rounded chamber. In its walls are five openings leading to the semicircular canals. These are tunnels in the bone having an elliptical or circular section, and opening at each end into the vestibule. The central line or axis of each canal lies nearly in one plane (which we may call the plane of the canal), and is approximately an arc of a circle. At one end of each canal there is an enlargement called the ampulla. The diagram (Fig. 1) represents a section through the axis of one of the canals.

The planes of the three canals are very nearly at right angles to one another. The canals are named from their position—the horizontal, the superior, and the posterior; the two latter unite at their non-ampullary ends before joining the vestibule, so that

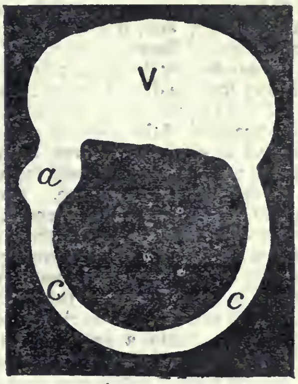

Fig. 1.

Section of bony labyrinth showing vestibule and one of the semi-circular canals. V, vestibule; *c c*, canal; *a*, ampulla.

there are five, and not six, openings into the vestibule—three ampullary, one for each canal, and two non-ampullary, one for the horizontal and one common to the superior and posterior canals.

The plane of the horizontal canal is nearly horizontal in the ordinary position of the head in all animals,[1] and is always at right angles to the mesial plane; the planes of the other two canals make nearly equal angles with the mesial plane. These relations are indicated diagrammatically in the accompanying sketch (Fig. 2), from which, to prevent confusion, the vestibule has been omitted.

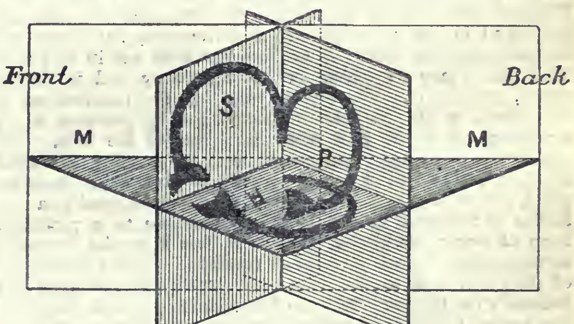

Fig. 2.

Diagram showing the relations of the planes of the three semi-circular canals of the left ear to each other and to the mesial plane. M M, mesial plane; S, P, H, the planes of the superior, posterior, and horizontal canals respectively.

In the bony labyrinth just described is inclosed a membranous labyrinth, similar in form, and consisting of the utricle, lodged in the vestibule, and of three membranous semicircular canals, each furnished with a membranous ampulla. The membranous labyrinth does not fit tight into its bony case—the utricle is much smaller than the vestibule (which contains, besides, other organs connected with the cochlea), and the diameter of the membranous canals is not more than one-fifth of that of the osseous canals. In the ampullæ the difference is not nearly so great; here there is only a narrow space between the bone and the membrane. The entire cavity is thus divided into two spaces, one within and one around the membranous labyrinth; each is filled with a liquid named the endolymph and the perilymph respectively. The external space contains, in addition to the perilymph, connective tissue attaching more or less firmly the membranous canals to the periosteum, and the blood-vessels and nerves which supply the membranous labyrinth. The nerves are distributed to a spot called the *macula acustica*, in the utricle,

[1] Recherches expérimentales sur les Fonctions des Canaux semi-circulaires et sur leur Rôle dans la Formation de la Notion de l'Espace. Par Elie de Cyon, M.D., &c., Lauréat de l'Institut de France.

[1] In man the plane of the horizontal canal slopes somewhat downwards and backwards, so that it becomes horizontal when the head is slightly bent forwards.

and to a crescent-shaped ridge, the *crista acustica*, near the middle of each ampulla. The nerves in each case end in hair cells, the hairs of which project into the endolymph. These nerves are derived from the vestibular branch of the so-called auditory nerve, or *portio mollis* of the seventh pair.

The remarkably regular, and, if we may use the expression, purpose-like arrangement of these organs must strike every one, and the mind naturally searches for the use of this curious geometrical apparatus. A theory long held, and not yet wholly abandoned, to which indeed Dr. de Cyon seems to attach some value, connects it with the perception of the *direction* of sound. The idea is not unnatural, and is obviously derived from the nearness of the apparatus to the organ of hearing and from the relation of its form to the three dimensions of space. No explanation has ever been given *how* it can serve this purpose, and a sufficient proof that it does not do so is supplied by the fact—easily tested by any one—that we have no means of knowing the direction of sound except by two or more simultaneous or successive observations. If a sound is heard louder in the right ear than in the left we conclude that it comes from the right, and by turning the head round we quickly obtain a sufficient number of observations to enable us to judge of the exact direction. If a sudden abrupt noise is made at a point equidistant from the two ears, we do not know its position unless we *see* what produces it. This theory may therefore be at once dismissed.

The first scientific inquiry into the function of the semicircular canals was made by Flourens in 1828. His experiments were conducted with an amount of care and the results described with a degree of accuracy and clearness not surpassed by any recent investigator. He observed that the section of a membranous canal was always followed by movements of the head, or even of the body of the animal *in the direction of the divided canal;* in other words, by oscillatory movements of rotation about an axis at right angles to the plane of the divided canal.

Flourens has been followed by various observers, Harless, Czermak, Brown-Sequard, Vulpian, and Löwenberg, who have confirmed the results above described, and referred them either to disturbances of hearing or to injury of the cerebellum.

An entirely new step was taken in 1870 by Prof. Goltz. Flourens had already hinted that the semicircular canals are concerned in the co-ordination of movements, but Goltz first devised a physical theory to explain how they act in this way. This theory may be called the statical theory, and is, shortly stated, as follows:—We may suppose that the terminations of the nerves in the ampullæ are stimulated by pressure or by stretching, as is the case with the nerves of the skin. The endolymph contained in the canals necessarily presses most upon that part of the wall of the cavity which is situated at the lowest point, and each position of the head will correspond to a particular distribution of pressure, and therefore to a particular form of nerve stimulation; we have thus a special sensation corresponding to each position of the head. That a knowledge of the position of the head and the power of regulating it is necessary for the preservation of the equilibrium of the body, was proved by Goltz by a very ingenious experiment. He fixed the head of a pigeon in an unnatural position by attaching its occiput to its breast, so that its beak was turned up and the vertex looked forward. He found that the animal so treated walked with great difficulty, and was quite unable to fly, and exhibited many of the phenomena observable in animals whose semicircular canals had been cut or destroyed.

The next investigations of importance as to the function of these organs are those of Prof. De Cyon in 1872. He repeated with great experimental skill, and with ingeniously-contrived modifications, the operations performed by Flourens and by Goltz, obtained the same results, and, guided by his medical observations on diseases accompanied by loss of equilibrium, formulated his theory as follows:—The semicircular canals give us a series of unconscious sensations as to the position of our heads in space; each canal has a strictly determined relation to one of the three dimensions of space; the loss of equilibrium and the other disturbances of locomotion caused by the section of the canals are solely due to the disorder of these sensations.

Before considering the next step in the development of the theory we must go back and examine the experiments on vertigo made by Purkinje about the time when Flourens first investigated the function of the semicircular canals.

Every one knows that if we stand up and turn round about a vertical axis and keep up this rotation for some time and then stop, we see, or think we see, surrounding objects moving round. Purkinje studied the conditions under which this apparent rotation occurs, and arrived at the following conclusions, which have been confirmed by all succeeding observers:—1. That the direction of the apparent motion of surrounding objects depends upon the direction of the preceding real motion of our body, and is always opposite to it. 2. That the axis about which the apparent motion takes place is always that line in the head which was the axis of the preceding real rotation. Thus, if we turn round with our head bent forward so as to look straight down at the floor, and then stop, keeping the head in this position, the apparent rotation takes place about a vertical axis; but if, when we stop, we lift up our head and look forwards, the apparent rotation takes place about a fore and aft axis, the fore and aft axis having been vertical while the real rotation occurred. A trick, illustrating this principle, is sometimes played on persons ignorant of this law of giddiness. They are asked to take a poker in their hand, plant it vertically on the floor in front of them, bow down so as to touch the end of the poker with their forehead, and walk quickly three or four times round the poker, then rise up and walk to the door. The apparent rotation takes place about a fore and aft axis, because the fore and aft line in the head was the axis of the real rotation; they see objects rise up on the one side and fall down on the other; the floor seems to incline itself to one side, and equilibrium becomes impossible. This experiment may be varied in many ways: thus, instead of the forehead, one ear may be placed on the end of the poker; the rotation then takes place about a right and left axis—the line from ear to ear. On rising, apparent rotation occurs about this line as an axis, and the floor in front seems to slope up or down according to the direction of the original real rotation.

Purkinje explained these phenomena thus:—"During the rotation of the body about its longitudinal axis, the brain, in virtue of its soft consistence, ought to have a tendency to remain a little behind the movement of the walls of the skull. This is the same phenomenon which we observe in a liquid when the vessel containing it is set in rotation. The particles of the liquid preserve their position relative to the external space, until their adhesion to the walls of the vessel forces them to take part in the motion of the latter. The cohesion of the brain is too great to allow of the reproduction of the same phenomenon exactly; but as the brain is soft and capable, to a certain extent, of internal displacement, it has some of the properties of liquids. We must therefore admit that a movement more or less intense must produce a displacement and relaxation of its parts, although an actual rupture of continuity cannot occur. Such distortions should produce the same disturbances as actual mechanical lesions, and differ from them only in degree."

This explanation is adhered to, in the main, by Dr. de Cyon, and although we do not admit that such tortional deformation of the brain is the chief or usual physical cause of the giddiness above described, it is probable that it has something to do with the phenomena when the rotation is very rapid and is suddenly stopped.

We now come to the modification of the theory of Goltz, which induced Dr. de Cyon to resume his experiments on the semicircular canals. This modification was made nearly at the same time by Prof. Mach, of Prague, Dr. Breuer, of Vienna, and Dr. Crum Brown, of Edinburgh. The papers in which they stated their views were written independently, and were published in the order above-mentioned within a period of about six weeks.

The views of the three observers are not quite identical, and it will be necessary to point out in what they differ; but they agree in so many details that a general description of their theory is possible. We have above called Goltz's theory *statical;* in opposition to it we may call the Mach-Breuer-Brown theory *kinetical.*

Goltz regarded the semicircular canals as organs which, by difference of pressure in different parts of the system, give us a notion of the *aspect* of the head in space. Mach, Breuer, and Brown regard them as organs which, by virtue of the *inertia* of the contained liquid and movable soft parts, give us a notion of the *change of aspect* of the head.

The simplest form of this theory is that in which it is stated by Dr. Breuer:—

"In a system of three ring-shaped tubes, approximately at right angles to one another, and filled with liquid, as is the case in the semicircular canals, there are produced by every

rotational movement of the whole system (that is, of the head) currents of liquid in a direction opposite to that in which the head is turned. The amount of the flow in each canal depends upon the plane in which the head is turned and upon the rate of the rotation. There are perfectly fixed relations between the rotational movement of the head and the currents in the inclosed liquid; if these currents can be perceived they will give us an exact account of the rotational movement of the head. We may regard, as possible organs for the perception of the currents, the so-called 'auditory hairs' which project at right angles inwards from a widened and flattened part of the canal; they are thus placed so as to be most sensitive to currents in the canal, and are on the other hand connected to nerves, of which they form the end-organs.

"To turn these facts to account in the sense of Goltz's theory we must assume that every flow of the endolymph, perceived by the ampullary nerves, produces a sensation of rotation of the head in the plane of the canal in which the flow takes place, and in a direction opposite to it, but that the perceptions of the six ampullæ of the two labyrinths combine to form a joint sensation. . . . .

"Our assumption has a necessary consequence. If the rotation of the head (of course along with the body) is kept up, the initial backward flow of the endolymph will be destroyed by friction against the walls. If the head then suddenly stops, the endolymph must, in virtue of its inertia, flow on in the sense of the rotation of the head; a sensation will therefore be produced of rotation of the head and body in a direction opposed to that of the previous rotation."

In this view the endolymph is held to lag behind the rotational movement of the head when this movement begins;—when the movement has continued at a uniform rate for some time, the endolymph is constrained, by fluid friction, to take part in the movement of the head, and if then the rotation of the head stops, the endolymph moves on. We have, thus, two ways in which a relative motion can occur between the endolymph and the walls of the cavity containing it:—1. When the head begins to move—here the walls leave the fluid behind. 2. When the head stops—here the fluid flows on. In both cases the sensation of rotation is felt. In the first this sensation corresponds to a real rotation, in the second it does not, but in both it corresponds to a real acceleration (positive or negative) of rotation, using the word acceleration in its technical kinematical sense.

Mach's view differs from Breuer's in this, that while Breuer assumes an actual flow of endolymph through the canals, Mach believes that the very narrow bore of the canals will preclude such a flow—the friction being so great that the most abrupt rotational movement of the head will not produce sufficient difference of pressure to cause an actual current. Instead of a current there will be produced a change of pressure in the ampulla, which would produce a current were the canal wider, and this change of pressure may be sufficient to act on the hair-cells, and irritate the ends of the nerves.

In Brown's statement of the theory, not the endolymph only, but the whole liquid and soft contents of the bony canals are supposed to lag behind the movement of the head, and in his first paper he suggested that there might be a relative motion between the bony and the membranous canals. This view, founded on the statement to be found in various anatomical text-books, that the membranous canals float nearly loose in the bony canals, is scarcely tenable when we know that the former are somewhat firmly attached at one side to the periosteum.

Another important point in which Brown's statement of the theory differs from that of Mach and from that of Breuer, lies in his regarding the two labyrinths as forming one organ, all the six canals of which are required to form a true conception of the rotatory motion of the head.

The doctrine of specific nervous action, now we believe generally accepted by physiologists, implies that while greater or less stimulation of an end-organ produces difference of sensation, a variety in the *mode* of stimulation cannot be perceived. Flow through the ampulla from the utricle to the canal on the one one hand, and from the canal to the utricle on the other, must produce a precisely similar sensation if the hairs of the hair-cells are equally moved. We must therefore look further for an explanation of our power of distinguishing between rotation in the one sense and rotation in the other sense about the same axis.

Mach was at first inclined to suppose that in each ampulla there are two sets of nerves each sensible to rotation in one sense only. He now adopts the explanation proposed by Brown, who based it upon the fact established by careful measurements in a considerable number of animals, that the *six* canals are sensibly parallel two and two. Thus the two horizontal canals are in the same plane, while the superior canal of one side is in a plane nearly parallel to that of the posterior canal of the other side. Further, in each of these three pairs (right and left horizontal, right superior and left posterior, right posterior and left superior), the two canals are so placed that when rotation takes place about the axis to which they are perpendicular, one of the two canals moves with its ampulla preceding the canal, so that the flow, or tendency to flow, is from ampulla to canal, while in the other the ampulla follows the canal and the flow, or tendency to flow, is from canal to ampulla. If, then, we suppose that flow from ampulla to canal—or, adopting Mach's view as stated above, *increase* of pressure in the ampulla—alone stimulates the hair-cells, while no effect is produced by flow in the opposite direction—or by *diminution* of pressure in the ampulla—we have in the six canals a mechanical system capable of giving us an accurate notion of the axis about which rotation of the head takes place, and of the sense of the rotation. To this explanation Dr. de Cyon objects that it assumes two organs, the superior canal of one side, and the posterior canal of the other side, which are not anatomically fellows, to be physiologically fellows. To this it is sufficient to answer that the motions which these two organs are supposed to perceive are produced by altogether different muscles. Let us take the case of the right superior and left posterior canal—the former is sensitive to rotation in one sense about an axis approximately passing through the left eye and the right mastoid process, a motion produced by muscles on the right side of the front of the neck, while the latter canal is sensitive to exactly the contrary motion about the same axis, and this motion is produced by muscles on the left side of the back of the neck. It is surely unreasonable to expect anatomical relations to exist between the organs perceiving two motions which do not exist between those producing them.

ALEX. CRUM BROWN

(*To be continued.*)

UNIVERSITY AND EDUCATIONAL INTELLIGENCE

WE have already referred to the mathematical courses for session 1878-9 in Johns Hopkins University, Baltimore. The following is the detailed programme:—I. Prof. Sylvester will lecture on (*a*) determinants, (*b*) modern algebra, (*c*) theory of numbers. II. Dr. Story will lecture on (*a*) higher plane curves, (*b*) solid analytic geometry, (*c*) quaternions, (*d*) elliptic functions. III. Mr. Craig will lecture on hydrodynamics. IV. Lectures will be given by appointed instructors on (*a*) differential equations, (*b*) analytic mechanics, (*c*) conic sections, (*d*) theory of equations, (*e*) differential and integral calculus. V. Mathematical Seminarium:—A Mathematical Seminarium is conducted under the guidance of the Professor and Dr. Story; it comprises all the instructors and students of mathematics in the university. At its monthly meetings, besides occasional papers, such topics as may from time to time suggest themselves in the course of reading to the students or instructors, or may otherwise be of general interest to persons pursuing mathematical studies, are made the subject of free oral discussion. VI. Scientific Association:—The Scientific Association of the Johns Hopkins University meets once a month for the discussion of subjects of general scientific interest. At these meetings an opportunity is afforded for communicating abstracts of recent mathematical progress, as well as the results of individual research. VII. Mathematical Journal:—"The American Journal of Mathematics" is published quarterly in the City of Baltimore, under the auspices of the Johns Hopkins University, and affords an efficient medium of intercourse between members of the university engaged in original investigation, and a wide circle of mathematicians in America and in Europe. VIII. All the mathematical journals published at home and abroad are taken in by the university. At the Peabody Library complete sets of "Crelle's Journal" and the most important scientific transactions are also accessible. The university library and reading rooms are open daily from 9 A.M. to 10 P.M.

THE Calendar of the Yorkshire College for its fifth session, 1878-9, forms a volume of 140 pages. The college has now day classes in the following subjects:—Mathematics, experimental

physics, chemistry, geology and mining, coal mining, biology, engineering, classical literature and history, modern literature and history, modern languages, oriental languages, and textile industries, and evening classes in all the above except experimental physics.

IN reference to the question of help for lectures to the scientific societies of English public schools, a correspondent sends a Harrow list as a suggestion to other schools. He believes that all the hon. members who are masters shown in the list have delivered addresses to the society; the rule always was to invite the most eminent among the strangers who gave lectures to become hon. members. Hence several well-known names connected with literature or science are among the latter.

THE Working Men's College, which was founded by the late Frederick Maurice, in 1854 (and which naturally sustained a heavy loss by his lamented death in 1872), with a praiseworthy desire to extend its usefulness, has arranged for a series of general and popular lectures, which are intended to be perfectly free, not only to Students of the College, but also to the general public. With this view the Council has managed to secure the aid of such men as Professors Corfield and Lowne, Dr. Casson and Mr. Frederick Harrison, all of whom take part in these lectures between this and Christmas. This attempt to render the public uses of the College much more prominent than heretofore will not, as it appears, in any way interfere with its ordinary and recognised functions, and will not in any degree impede its class teaching, which has always been of the highest character. Various courses of scientific lectures by Mr. Dunman and Mr. Owen are announced.

SCIENTIFIC SERIALS

Journal of the Cincinnati Society of Natural History, July. Vol. i., No. 2.—This number gives earnest that good work is meant by the members. Its contents are chiefly interesting to palæontologists, who will find in it a list of lower silurian fossils of the Cincinnati group, by Messrs. J. Mickleborough and A. G. Wetherby, together with descriptions of many new forms found in these strata, by Messrs. Ulrich and Miller.

Reale Istituto Lombardo di Scienze è Lettere, Rendiconti, vol. xi. fasc. xiii.—We note the following papers in this number:—Causes and circumstances influencing hereditary transmission in animals (continued); Participation of the nervous system in the phenomenon of fecundation, by Signor Lemoigne.—Anæsthesia and anæsthetics in mediæval surgery, by Prof. Corradi.—Influence of water on the spinning of the cod of the silkworm, and on the quantity and quality of the silk, by Prof. Gabba and S. Textor.—On some facts relating to saccharification of amides in the digestive process, by Dr. Solera.

Journal of the Franklin Institute, August.—This number opens with a discussion, by Mr. Isherwood, of some instructive experiments on the expansion of steam in the steam-engine.—A new method of grinding glass specula is described by Prof. Elihu Thomson, the principle of it being the fact that when two equal discs of glass or other material are ground together, one above the other, the under one always becomes convex, while the upper one becomes concave, and by making the strokes of the upper disc wide and sweeping, this change of form may be greatly accelerated.—Dr. Morton gives an account of the singing telephone as made at the Stevens Institute of Technology.—A new method of reduction for diffraction spectra observations is communicated by Dr. Rosenberg.—The problem of perforated pipes, as applied to "sprinklers" (a pipe system lately introduced into cotton-mills for preventing the spread of fires), is investigated by Mr. Frizell.

SOCIETIES AND ACADEMIES

PARIS

Academy of Sciences, September 30.—M. Fizeau in the chair.—The following papers were read:—Formation of an astronomical museum at the Observatory of Paris, by M. Mouchez. This is to include portraits of astronomers and *savants*, a collection of medals, drawings and photographs of celestial objects and phenomena, ancient instruments, &c.—Experimental facts showing that abundant sudoral secretions are not necessarily connected with excessive activity of cutaneous circulation, by M. Vulpian. In a dying cat, *e.g.*, when the heart's action is much weakened, and the digital parts are bloodless, the sweat exudes freely from these parts.—Remarks on the phonograph and the telephone, by M. Bouillaud.—Determination of the exact number of irreducible co-variants of the binary cubo-biquadratic system, by Prof. Sylvester.—Industrial utilisation of solar heat, by M. Mouchot. This describes experiments made during the Exhibition. *Inter alia*, he set in action, on September 2, a solar receiver with mirror having an aperture of about twenty square metres. It had, at the focus, an iron boiler weighing, with accessories, 200 kilogrammes, and having a capacity of 100 litres (30 for the steam chamber and 70 for the liquid). In half-an-hour the 70 litres were raised to boiling, and the manometer soon registered 6 atm. pressure. On September 22, with slightly veiled sun, he got 6·2 atm., and worked, under a pressure of 3 atm., a Tangye pump raising 1,500 to 1,800 litres of water hourly to the height of 2 m. With a clear sky on the 29th ult. 7 atm. was reached.—Discovery of a small planet at the observatory of Ann-Arbor, by Mr. Watson.—On intra-mercurial planets, by M. Gaillot.—On molecular attraction in its relations to the temperature of bodies, by M. Levy. To know all the isothermal and all the adiabatic lines of a body, and so to be able to study it completely, it is necessary and sufficient to know *two* of its isothermal lines and *only one* of its adiabatic lines.—On losses of charge produced in the outflow of a liquid when the section of the flow undergoes a sudden increase, by M. Boussinesq.—On the rotary power of quartz and its variation with the temperature, by M. Joubert. The angular coefficient of the curve of variation increases at first pretty rapidly up to 300°. From this to 840° (the boiling point of cadmium) it is nearly constant and the curve nearly a straight line with point of inflexion about 500°. Beyond 840° and up to 1,500°, the rotatory power increases only with extreme slowness. With a quartz of 46·172 mm., giving a rotation of 1,000° at zero, the increase from 300° to 900° is twelve minutes per degree. With a quartz of only 11 mm. the increase would still be three minutes per degree. Thus quartz makes an extremely sensitive thermometer, with the essential condition of comparability.—Phonic wheel for regularisation of the synchronism of motions, by M. Lacour. An iron-toothed wheel turns with its teeth very near an electro-magnet which is caused to exert periodic attraction by means of a vibrating diapason.—On the presence of isopropylic, normal butylic, and secondary amylic alcohols in the oils and alcohols of potatoes, by M. Rabuteau.

CONTENTS

THURSDAY, OCTOBER 17, 1878

ON THE SCIENCE OF EASY CHAIRS

THERE is a reason for everything, if we can only find it out, but it is sometimes very hard to discover the reasons of even the very simplest things. Every one who has travelled much, and even those who have merely looked through books of travels, must have been struck by the variety of attitudes assumed by the people of different countries. The Hindoo sits down on the ground with his knees drawn up close to his body, so that his chin will almost rest upon them; the Turk squats down cross-legged; the European sits on a chair; while the American often raises his legs to a level with his head. Nor are the postures assumed by the same people under varying circumstances less diverse. Climate or season, for example, will cause considerable alteration in the posture assumed, as was well shown by Alma Tadema, in his pictures of the four seasons exhibited in the Academy a year ago. In his representation of summer he painted a woman leaning backwards on a ledge, with one leg loosely hanging down, while the other was drawn up so that the foot was on a level with the body. In the picture of Winter, on the other hand, we saw a figure with the legs drawn up in front of the belly. The reason for these different postures has been explained by Rosenthal. The temperature of the body, as is well known, is kept up and regulated by the circulation of the blood through it, and a great proportion of the blood contained in the whole body circulates in the vessels of the intestines. Now the intestines are only separated from the external air by the thin abdominal walls, and therefore any change of temperature in the atmosphere will readily act upon them, unless they be guarded by some additional protection. The Hindoos are well aware of this, and they habitually protect the belly by means of a thick shawl or cummerbund, thus guarding themselves against any sudden change of temperature. This precaution is also frequently adopted by Europeans resident in hot climates, and is even retained by them after returning to England. But the function of the cummerbund may, to a certain extent be fulfilled by change of posture alone. When the legs are drawn up, as in the picture of Winter already referred to, the thighs partially cover the abdomen, and taking the place of additional clothing, aid the abdominal walls in protecting the intestines and the blood they contain from the cooling influence of the external air.

Thus it is that in cold weather, when the quantity of covering in bed is insufficient, persons naturally draw up their legs towards the abdomen, so as to retain as much heat as possible before going to sleep. In hot weather, on the contrary, they wish to expose the abdomen as much as possible to the cooling influence of the atmosphere. The posture depicted by Alma Tadema is the most efficient for this purpose. It no doubt answers the purpose to lie down flat on one's back, but in this position the abdominal walls are more or less tight, whereas, when one of the legs is drawn up as in the painting just alluded to, the walls are relaxed, and, the intestines not being subject to any pressure, the blood in them will circulate more rapidly, and the cooling process be carried on more effectually. In this attitude also the thighs are completely separated and loss of heat allowed from their whole surface.

Varying conditions of fatigue also alter the postures which people assume. When slightly tired one is content to sit down in an ordinary chair in the position of the letter N with the middle limb horizontal. As we get more and more fatigued we usually assume positions in which the limbs of the N become more and more oblique, the trunk leaning backwards and the legs extending forwards. If we lie down in bed on our back the legs will probably become straight, but if we rest upon our side they will be more or less bent. The straightness of the legs in the supine position is simply due to their weight, which is then supported at every point by the bed, but when we lie on our sides the genuflexion of the legs is most agreeable, because not only are the muscles more perfectly relaxed, but, as the late Prof. Goodsir pointed out, the bones which form the knee-joint are slightly removed one from another, and thus the joint itself, as well as the muscles, passes into a state of rest. Some of the bamboo easy chairs manufactured in India allow us to obtain the advantages of both positions. These chairs are made in the form of a somewhat irregular straggling W, and in them one can lie on one's back with every part of the body thoroughly supported, and the knees bent in the same way as they would be if one lay upon one's side.

Thus simple inaction, the relaxation of muscles, and the laxity of joints, are some of the factors necessary for complete rest, and an easy chair, to be perfect, must secure them all.

But it is possible for an easy chair to secure all these, and yet be imperfect. We have just said that usually, as the fatigue becomes greater and greater, the tendency is to assume the position of the N with the limbs at a more or less obtuse angle, but when sitting in an ordinary chair we find relief from raising the feet by means of a footstool, although this tends to make the angles of the N more acute instead of more obtuse. Still more relief, however, do we obtain when the legs are raised up on a level with the body by being placed upon another chair, or by being rested on the Indian bamboo seat already described. If, in addition to this, the legs are gently shampooed upwards, the sensation is perfectly delightful, and the feelings of fatigue are greatly lessened. To understand how this can be, it is necessary for us to have some idea as to the cause of fatigue. Any muscular exertion can be performed for a considerable time by a man in average health, without the least feeling of fatigue, but by and by the muscles become weary, and do not respond to the will of their owner so readily as before; and if the exertion be too great, or be continued for too long a time, they will ultimately entirely refuse to perform their functions. The muscle, like a steam-engine, derives the energy which it expends in mechanical work from the combustion going on within it, and this combustion, in both cases, would come to a standstill if its waste products or ashes were not removed. It is these waste products of the muscle which, accumulating within it, cause fatigue, and ultimately paralyse it. This has been very neatly shown by Kronecker, who caused a frog's muscle, separated from the body, to contract until it entirely ceased to respond

to a stimulus. He then washed out the waste products from it by means of a little salt and water, and found that its contractile power again returned, just as the power of the steam-engine would be increased by raking the ashes which were blocking up the furnace and putting out the fire. These waste products are partly removed from the muscles by the blood which flows through them, and are carried by the veins into the general circulation. There they undergo more complete combustion, and tend to keep up the temperature of the body. At the same time, however, according to Preyer, they lessen the activity of the nervous system, producing a tendency to sleep, and in this way he would, at least to some extent, explain the agreeable drowsiness which comes on after muscular exertion. It would seem, however, that the circulation of the blood is insufficient to remove all the waste products from the muscles, for we find that they are supplied with a special apparatus for this purpose. Each muscle is generally ensheathed in a thin membrane, or fascia, and besides these we have thicker fasciæ ensheathing whole limbs. These fasciæ act as a pumping apparatus, by which the products of waste may be removed from the muscles which they invest. They consist of two layers, with spaces between. When the muscle is at rest these layers separate and the spaces become filled with fluid derived from the muscle, and when the muscle contracts it presses the two layers of its investing sheath together, and drives out the fluid contained between them. This passes onwards into the lymphatics, where a series of valves prevent its return, and allow it only to move onwards, till at last it is emptied into the general circulation.

In strong and healthy people the veins and lymphatics together are quite able to take up all the fluid which the arteries have supplied to the muscles, and thus prevent any accumulation from taking place either in them or in the cellular tissue adjoining them, or at least prevent any such accumulation as might become evident to the eye. In delicate, weakly persons, or in those who suffer from certain diseases of the vascular system, this is not the case ; and after standing or walking for a long time the legs become swollen, so that the boots feel tight, and sometimes even a distinct impression may be remarked at that part of the ankle which was covered by the boot. In such persons we can actually see the swelling disappear, after the feet have been kept rested for some time on a level with the body, and it may be removed more quickly still by gently and steadily rubbing the limbs in one direction from below upwards. It is almost certain that what we thus see in weakly persons occurs to a slighter extent in all, and that even in the most healthy person after a long walk a slight accumulation of fluid, laden with the products of muscular waste, occurs both in the muscles themselves, and in the cellular tissue around them, even although we cannot detect it by simple inspection. So long as the limbs of such a person hang down, the force of gravity retards the return both of blood through the veins and of lymph through the fasciæ and lymphatics, and thus hinders the muscles from getting rid of those waste products which caused the fatigue. When the legs are raised, this hindrance is at once removed, both blood and lymph return more readily from the muscles, carrying with them those substances which had been formed by the muscles of the limbs during the exertions which they had undergone when carrying the body about. So long as these substances remained where they had been formed, they might cause in the muscles of the legs an undue amount of fatigue, although when distributed over the body generally, they may produce only a pleasing languor. When the legs are long, the obstruction to the return of blood and lymph is of course greater than when they are short, and this return will take place more readily when the legs are raised above the body than when they are only on a level with it. This may be one of the reasons why some of our long-legged American cousins are so fond of raising their feet to a level with their heads, or even higher, although it is very probable that there are reasons still more powerful, which we may discuss at a future time.

It has already been mentioned that the lymph is propelled along the interstices of the fasciæ into the lymphatic vessels by the intermittent pressure which the muscle exerts upon them from within, and it seems natural to suppose that the flow may also be aided by a pressure from without, in the form of shampooing. Even when the hand is rubbed backwards and forwards upon the leg it will relieve fatigue, but the relief is greater when the leg is firmly grasped and the hand moved gently upwards so as to drive onwards as much as possible any fluid which may have accumulated in the limb, and the grasp being then relaxed, the same process should be repeated.

But while the lymph is thus most readily removed by the pumping action of intermittent pressure either of the hand without or of the muscles alternately contracting and relaxing within, it seems to us probable that this process may also be aided by steady, constant pressure from without. No doubt it is impossible for such a steady pressure to take the place of the regular pumping action produced by the alternate contraction and relaxation of the muscles when in action, yet it will have a somewhat similar action, though to a very much less extent. For at each beat of the heart, as Mosso shows, the entire limb is distended by the blood driven into the vessels, and during the pauses between the beats it again becomes smaller. Each pulse, therefore, by distending the whole limb and each individual muscle will press out a little of the fluid contained in the fasciæ in the same way as the contractions of the muscles themselves, and it seems to us probable that it is the aid which is afforded to this process by the gentle pressure exerted on the outside of the legs by a seat which supports them along their whole extent, that renders such a seat so peculiarly restful and agreeable. For an easy chair to be perfect, therefore, it ought not only to provide for complete relaxation of the muscles, for flexion and consequent laxity of the joints, but also for the easy return of blood and lymph not merely by the posture of the limbs themselves, but by equable support and pressure against as great a surface of the limbs as possible.

Such are the theoretical demands, and it is interesting to notice how they are all fulfilled by the afore-mentioned chair in the shape of a straggling W, which the languor consequent upon a relaxing climate has taught the natives of India to make, and which is known all over the world.

SCIENTIFIC BALLOONING

Histoire de mes Ascensions. Recit de Vingt-quatre Voyages aériens (1868-1878) *précédé de simples Notions sur les Ballons et la Navigation aérienne.* Par Gaston Tissandier. Illustré de nombreux dessins par Albert Tissandier. (Paris: Dreyfous, 1878.)

M. TISSANDIER has just published a handsome and well-illustrated volume, giving a history of his twenty-four ascents with an account of their scientific results, which are of very considerable importance. M. Tissandier is one of the most scientific of modern aeronauts, and has, by his ascents, made important additions to our knowledge of atmospheric phenomena. The work to which we refer ought to interest many readers; it is not only full of adventures, of "hairbreadth 'scapes," of humorous incidents, and beautiful descriptions of atmospheric scenes, which ought to prove attractive to the general reader, but contains, besides, a large amount of data of great importance in connection with the physics of the air.

Aeronautics, M. Tissandier tells us, may be divided into five distinct branches:—1. The balloon itself. 2. Meteorological aerostation, in the scientific exploration and study of the atmosphere. 3. Military ballooning, captive aerostats, military reconnaissances, the aerial post. 4. Direction of aerostats and aerial navigation. 5. "Aviation," or mechanical flight, the principle of which has been designated under the phase "heavier than air." In the first part of M. Tissandier's work will be found a *résumé* of the principal events in the history of aeronautics, from the first rude attempts down to the magnificent captive balloon of M. Giffard, which has excited so much attention during the Paris Exhibition. The author gives an account of the present state of aerial navigation, and shows what may be expected in the future, judging from facts submitted to the test of scientific reasoning.

The second part of M. Tissandier's work contains an extremely interesting and scientifically valuable account of twenty-four aerial voyages made by himself. It is about ten years since M. Tissandier made his first ascent, and the greater number of his ascents have been made in company with his brother, M. Albert Tissandier, who by the aid of his pencil has recorded the ever new, always interesting, and often incomparable spectacles which the atmosphere opens to the eye of the explorer. Many of his sketches are of great meteorological, as well as artistic, value. In the second part of the work an explanatory diagram indicates exactly the route taken during each journey, the altitude attained, the nature and situation of the clouds, the direction of the currents, their temperature and the atmospheric circumstances connected with them. Numerous wood engravings, from drawings by M. Albert Tissandier, represent the marvellous spectacles observed, the effects of clouds, sunsets, and the various optical phenomena witnessed during the journeys described. Indeed, the work is so luxuriantly got up, and so profusely illustrated, that we are bound to infer either that M. Tissandier's publisher is unusually generous or that France must possess a considerable reading public of more than average intelligence.

The work contains a detailed description of the structure of M. Giffard's monster captive, to the understanding of which the many well-executed illustrations are a great help. An appendix gives the interesting experiments as to carbonic acid in the air made in the *Zenith* by MM. Tissandier and Mangon, and a detailed description of Giffard's new apparatus for the preparation of hydrogen in large quantities.

In a recent lecture at the Sorbonne M. Tissandier endeavoured to point out some of the important services which aeronautics might be made to render to science. A purely theoretical science has necessarily few admirers. It should not be so, however, with the investigation of aerial phenomena. This important department of the physics of the globe is not only useful to the sailors and agriculturists of all nations; it is also of great service in public hygiene. But in order that meteorology, quite a modern science, might be instituted, there should be no doubt of the materiality of the air, thanks to the conceptions of the Galileos, Torricellis, and Pascals. The Meteorological Society of the Palatinate was only founded in 1781; only then were registrations of atmospheric variations begun. The invention of the telegraph soon permitted simultaneous observations to be made, and centralised and led to the hope that prevision of the weather would cease to be an unrealisable chimera. M. Tissandier points out how serviceable to oceanic and river navigation are the warnings transmitted by the International Meteorological Service to the principal maritime stations. The organisation of this service enables us to follow effectively the progress of centres of depression, to discover and announce the general direction of winds, to figure their spirals across space, to establish the curves of the isobaric lines or lines of equal pressure; better still, to prevent, by means of the telegraph, more rapid even than the tempest, a great number of shipwrecks and accidents on coasts.

To discover the real cause of the movements of the air, of cyclones, of the mode of formation, of the direction and variations of the rate of winds, it is necessary, to use the expression of Biot, "prendre la météorologie par en haut," *i.e.*, to seek in the elevated regions of the atmosphere the explanation of the phenomena which occur at the bottom of the aerial ocean where human destinies are accomplished. In fact, "it is in the high regions of the air that meteors are formed, rain, snow, hail; it is there that the lightning traces its furrow, and the thunder rolls; it is there that the aurora borealis displays its plume of light, and that the aerolite shines forth and bursts. There are the upper currents which chariot the clouds. It is to these elevated regions that the science of meteorology ought to be directed."

The observer has the choice between two distinct methods of exploration. He may ascend the mountains or mount in a balloon. No doubt the former process appears at first most secure, but it is seen that the second presents, practically and theoretically, superior advantages, offers most security, and is attended with better results. It suffices to recall the obstacles encountered, the dangers incurred by a tourist guide, the obscure protagonist of the memorable labours of De Saussure, the energetic Jacques Balmat. If he was the first, in August, 1786, to strike his iron-shod staff on the crest of the giant of the Alps, it was only after many fruitful

experiments, and after having encountered many perils, and endured much suffering. With the balloon, however, there is less delay, less fatigue: "I launch," said Charles, "into the air like a bird uncaged; in ten minutes I am at a height of 10,000 feet."

If, besides, the aerostatic way is more accessible than the slope of the mountains, it is also preferable from the technical point of view. It is to be remarked, in fact, that the air of high mountains is always subject to the influence of surrounding glaciers. Moreover, these powerful geological reliefs are only formed at certain points of the earth's surface. We must not only climb, but often go far in search of these abrupt and gigantic ladders, while, by means of the balloon, we reach, almost unconsciously, with a rapidity which is prodigious, the laboratory of the principal atmospheric phenomena. M. Tissandier does not deny the utility of observatories like those of the Puy de Dôme and the Pic du Midi, valuable establishments when the services of men like M. Alluard and General de Nansouty can be obtained. The problems of the high regions demand for their solution more than one indefatigable investigator, and, whatever be the mode of investigation followed, the more numerous the workers, the sooner will success crown their efforts.

How many questions are there to solve however! Among the most interesting, and those which are now almost solved, since the researches of M. Tissandier, let us note the presence, in atmospheric dust, of spherules of the magnetic oxide of iron whose diameter scarcely exceeds the 500th part of a millimetre. These spherules, which contain nickel, present a striking analogy of composition with meteoric stones, and have evidently an extra-terrestrial origin. They have been observed in glaciers, in dust-showers like those driven by the wind of the desert; their appearance has been noticed after the explosions of bolides. The sediments left by rain-water present traces of them, and M. Tissandier himself has collected them on the upper steps of the stairs of the tower of Notre-Dôme.

To return to ballooning. Since the discovery of the brothers Montgolfier, since the experiments of Charles, Pilâtre, and the Marquis d'Arlandes, scarcely a century has passed, and yet we can count more than 20,000 ascents. In this number, unfortunately, it would be difficult to find more than 100 undertaken with an exclusively scientific purpose, and with the indispensable instruments of observation.

It was the physicist Robertson who, in 1803, commenced the series of scientific explorations of the air. Biot and Gay Lussac, in 1834, then Gay Lussac alone, accomplished ascents which are important events in meteorological investigation. In 1850 MM. Barral and Bixio made an ascent characterised by very remarkable circumstances. At the height of 7,000 metres they met with a cloud formed, not of vesicles of water, but of spangles of ice. The phenomenon has, moreover, been observed in many other aerial journeys.

M. Tissandier mentions in his book, in a very special manner, the magnificent enterprises of his venerable friend, Mr. James Glaisher, who has made more than thirty aerial voyages, almost always to very great heights. We owe to him observations of great interest, which shed a clear light on many questions, among others on those which refer to the decrease of temperature of humidity in the various strata of air. In later times MM. Camille Flammarion and De Fonvielle have devoted themselves to aeronautics, not without profit to science. Croce-Spinelli and Sivel, also, had made their *début* as masters; their tragic fate, and the miraculous escape of M. Tissandier, our readers must remember. This disastrous journey is fully described in the volume before us.

M. Tissandier endeavours to prove that the direction of the upper atmospheric currents, their rate of translation, their temperature, and their hygrometric state, can only be surely established by means of the aerostat, the observer on the earth being only able to appreciate those elements with reference to superficial winds—simple accidents which ought not to be confounded with the true aerial rivers which often roll their enormous masses above the clouds themselves.

There is room to hope, moreover, that the balloon, which has already received notable improvements, may become, at no distant day perhaps, a directable instrument, and traverse the fields of air as a ship ploughs those of the sea. With these attempts at obtaining control over the course of the balloon, the name of M. Henri Giffard is closely connected. Those who wish to form some idea of what the balloon is capable as an aid to the meteorologist and as a means of investigating the physics of the atmosphere, could not do better than read M. Tissandier's handsome work.

OUR BOOK SHELF

Proceedings of the Aberdeenshire Agricultural Association, 1876-78.

It has been a subject of frequent regret that while Germany and France have been active in carrying out investigations upon agricultural questions few systematic efforts in this direction have been made in our own country. We learn, therefore, with pleasure that two centres for agricultural investigations have recently been started in Scotland—one by the Aberdeenshire Agricultural Association, the other by the Highland Society. The reports of the Aberdeenshire Association for 1876 and 1877 are now before us, and demand a short notice.

The subject selected for investigation has been the turnip crop, the special object of the experiments being to ascertain the value of various forms of phosphatic and nitrogenous manures. It is impossible not to admire the pains spent on this investigation, but we are sorry to say it is equally evident that the work has been done with very little knowledge of the facts ascertained by earlier investigators of the subject. Labour is consequently spent in proving that which stands in no need of proof, while discoveries are proclaimed of facts already well known to chemists.

One principal point which the experiments are considered to have established is the little superiority of the soluble phosphate of calcium over the insoluble as a manure for turnips. Farmers are told to purchase phosphates in whatever form may be the cheapest, without reference to solubility. This is indeed a startling proposal. Mineral phosphates are at the present day treated with sulphuric acid on a very large scale, with the sole object of producing a superphosphate in which all the phosphoric acid shall be in a soluble form: this mode of treating phosphates is clearly according to the present report an entire mistake. On what experiments is this conclusion based? Will it be believed that in nearly

every case the experiment consisted in a comparison of the manuring effect of three parts of phosphoric acid in an insoluble form, with a mixture containing one part of soluble and one part of insoluble phosphoric acid. The result was somewhat in favour of the latter mixture. It will be seen at once that the experiment afforded no fair comparison of the two forms of phosphate. Besides the fatal error of mixing the soluble and insoluble phosphates together, and comparing them in unequal quantities, the amount applied to the land was far too large. Let them drill with one set of turnips 2 or 3 cwts. of superphosphate in which the whole of the phosphoric acid is soluble, and apply to another plot the same amount of phosphoric acid in the so-called insoluble form, and the result of the comparison will be very different to that at present shown.

In speaking of the effect of nitrogenous manures the report correctly states that they produce but little effect on the turnip crop. The fact is that turnips have a greater power than most farm crops of assimilating the nitrogen of the soil, and being thus able to feed themselves stand in little need of artificial help. Where, however, the soil is in an exhausted condition, nitrogenous manures will always produce a marked effect.

The analyses of the turnips grown by the experimental manures supply a variety of "new and unexpected information." Much of this is true in substance, but is already well known to agricultural chemists. We abstain from criticising, for we are sure the next report will show a far better acquaintance with the chemistry of the subject, and that the industry and zeal now displayed will finally issue in real additions to our knowledge of agricultural science.

Euclid. Books I. and II. Edited by W. H. H. Hudson, M.A. *Algebra.* By the Same. (London: The Society for Promoting Christian Knowledge).

THE Euclid is founded on Simson's second edition (1762). In addition to the text there are a few definitions and some judicious explanatory notes. The Algebra (or Primer as the author styles it) is divided into three parts, Part I. Notation, Addition, and Subtraction; Part II. Multiplication, Division, and Simple Equations; Part III. Measures and Multiples, Fractions, and Quadratic Equations. The proof here given of $-a \times -b = ab$, due to Euler, appears to be quite sound. Mr. Hudson states his belief that this proof was misunderstood by Mr. Mill in his criticism ("Logic," vol. ii., ninth edition, p. 408). This little work is an excellent one, and contains a vast amount of good matter in a small compass. Mr. Hudson has performed his task in no perfunctory manner. Both books are brought out with a view to teaching the subjects of which they treat as required by the new code. They are very neatly printed and got up.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to ensure the appearance even of communications containing interesting and novel facts.*]

The Magnetic Storm of May 14, 1878

IN regard to the communication on the magnetic storm of May 14, 1878, which appeared in NATURE, vol. xviii. p. 617, it may be interesting to add some particulars furnished by examination of the magnetic photographs of the Royal Observatory.

For some days preceding May 14 the trace of the declination magnet had been very quiet, exhibiting only the ordinary diurnal change; but on May 13, at 18h. 5m., Greenwich mean time, the character of the curve abruptly and distinctly changed, small and frequent oscillations commencing then to be shown. At about 6h. on May 14 the north end of the needle began to move gradually in an easterly direction, and at about 9h. had reached a position twenty-five minutes of arc east of its usual position, the small oscillations still going on. No great change then occurred until 11h. 45m., when the north end of the needle began to move sharply westward. At midnight it had moved twenty minutes westward, occupying then its usual position nearly; almost immediately, however, it turned again eastward, and at 12h. 40m. had moved twenty minutes in that direction; after this time, with the exception of two smaller bends, no other unusual motion occurred, and the magnet gradually resumed its ordinary position. The small oscillations first spoken of ceased at about the time of the commencement of the first rapid motion, at 11h. 45m.

The commencement of the disturbance is not so distinctly perceptible in the trace of the horizontal force magnet, but continued small oscillations occur through the evening of May 14. At 11h. 45m. the northerly force had (gradually since 6h.) decreased nearly 0·01 part of the whole horizontal force; it then increased rapidly, and at midnight had about reached its usual magnitude; by 12h. 40m. it had again considerably diminished (but less than before), and after this time the magnet gradually resumed its usual position. The small oscillations ceased about midnight.

The vertical force magnet trace shows a few very small oscillations during the evening; after 7h. the force decreased gradually till midnight; at the latter time a sharper decrease occurred; at 12h. 30m. the force had altogether diminished by about 0·003 parts of the whole vertical force; after this time the magnet, rather rapidly at first, but afterwards more gradually, returned to its ordinary position.

The first start in the trace of the declination magnet, at 18h. 5m., is most distinct; the character of the trace definitely changes at that time. If the commencement of disturbance is as sharply indicated in the China, Melbourne, and Stonyhurst registers, we shall have here a well-established instance of simultaneous, or nearly simultaneous, action, at widely-separated parts of the earth's surface. The disturbance practically ceased at Greenwich, May 14, 16h. It was comparatively large as occurring in an otherwise quiet year. In years of activity these motions of the magnets, in amount, are, on many days, much exceeded.

WILLIAM ELLIS

Royal Observatory, Greenwich, October 12

P.S.—Earth currents were active at Greenwich during the whole period of the magnetic disturbance.

Cyclones and the Winter Gales of Europe

MR. S. A. HILL, in NATURE, vol. xviii. p. 617, compares together the number of hours of high wind in the British Isles with the number of West Indian cyclones observed in each year from 1869 to 1874. It may be interesting to add the result given by the Royal Observatory register. The hourly values of velocity in the years mentioned have not yet been tabulated, but adopting for comparison the number of days on which the daily velocity exceeded 500 miles, we have counted up the number of such days in each year, which numbers, for more ready comparison with those given in NATURE, we have multiplied by a constant. The comparison with the values previously printed in NATURE then stands as follows:—

	1869	1870	1871	1872	1873	1874
Cyclones (W. Indies)	0	7	3	0	1	?
Hours of high wind (British Isles) ...	714	570	537	679	571	658
Days of high wind, Royal Observatory, × 25	975	525	175	725	750	575

Height and Shape of Mount Hekla

I NOTICE that there is a mistake in regard to the height of Hekla in the map which accompanies my account of the eruption of February 27, 1878, for which I fear I am alone responsible. It is there stated to be 4,950 feet. The real height is 4,961 *Danish* feet = 5,108 English feet. The height has been frequently misstated. Sometimes it is asserted to be

5,700 feet, while on the other hand it has been placed as low as 4,300. It is not probable that the height has altered during the last century, for although some writers have asserted that the mountain lost 500 feet during the eruption of 1845, it has been satisfactorily proved that the crater of 1845 opened in the side of the mountain below the principal craters. The previous eruption was in 1772. Hekla is often spoken of as if it were the only volcano in Iceland, while in reality the whole island is dotted over with volcanic vents, of which Hekla is indeed the most frequently active, but by no means the highest. In fact, there are four higher mountains in the island, the highest being Oræfa Jökull—6,426 English feet.

Secondly, as to the shape of Hekla. Volcanoes often present a fairly symmetrical conical form, as we should expect from their mode of formation. This is specially the case in regard to Etna. But Hekla presents rather the appearance of a hog's back. Seen from the north or south it has a long oval outline, serrated by virtue of its three craters, and with an axis which passes from north-east to south-west. Thus the ends of the oval mass alone present the usual conical appearance of volcanoes. It is rather a line of craters than a single one; a volcanic rift elevated above the plain, with large *bocche del fuoco*. These rifts are common in all volcanic countries. In Iceland we have a notable example in Köetlagia, as we commonly call the volcano; in reality *Köetla-gja*—the Köetla rift, along the line of which various vents of fire exist. So again we have Almannagjá, the great rift at Thingvellir. In the eruption of Etna, which took place in 1865, a large rift opened in the side of the mountain, and along the line of it no less than seven small craters opened. In the last eruption of Hekla fourteen small craters opened in a line. We have to distinguish between volcanoes terminated by one large crater, which always furnishes the vent when the eruption takes place from the summit, and volcanoes terminated by a line of craters, one or other of which may be active at any one time. To the former class belong Etna and Vesuvius, to the latter Hekla and Köetla-gjá.

Apparently we cannot get out of the way of spelling Hekla *Hecla*. In one of our leading journals of October 11 I notice the spelling *Hecla*. Hekla means *hooded*, in allusion to the covering of snow, or of cloud, which so frequently rests upon its summit. *Hökull* signifies a chasuble in Icelandic. According to some writers Mount Pilatus, near Lucerne, takes its name from *Pileatus*, in allusion to its cloud-capped summit.

Marlborough College, October 13 G. F. RODWELL

Animal Intelligence

As many of the readers of NATURE have probably not seen my article on the above subject in the current number of the *Nineteenth Century*, I feel it desirable to repeat in these columns the request with which that article concludes. This request is merely that those who read it should favour me by sending to the under-mentioned address brief accounts of any well-marked instances of the display of animal intelligence which may have fallen within their own notice or that of their friends. None of these instances will be published by me without permission; but I desire to accumulate as many of such instances as possible—no matter of how dubious a character—in order that I may obtain a wide basis of suggestion as to the directions in which experiments may be most profitably employed. I may add that as the effect of publishing this invitation in the *Nineteenth Century* has been that of burying my desks in a snow-storm of letters, I should like to take this opportunity of explaining to past and future correspondents that I do not esteem their kindness the less because its bounty is too great for me to acknowledge in individual cases. GEORGE J. ROMANES

The Microphone as a Receiver

I HAVE made some experiments which seem to throw light on the fact mentioned by Prof. Hughes and also by Mr. Blyth (NATURE, vol. xviii. p. 172), that the microphone, or a jar with gas cinders, may act as a receiver.

A Morse-key is set on a sounding-box; one pole of an intermitting current is connected with the lever; the other pole with the fore-part of the key (which for telegraphing purposes is connected with the positive pole of the sending battery). By regulating the screw, which is found at the after-part of the key (which for telegraphing purposes is connected with the coil of the electro-magnet), a slight contact is made between the lever and the fore-part of the key, and directly a very distinct sound is heard of the same character as that of the sound emitted by the interrupting apparatus.

A very good form of the same experiment is the following:—A leaden cylinder and a rocker are taken as used in the experiment of Trevelyan; the rocker is placed on the cylinder, and is, moreover, supported by a sharp edge; if necessary pressure downwards is applied on the stem, in order to prevent the pressure of the rocker on the cylinder being too great. The cylinder is connected with one pole of the intermitting current, the stem of the rocker with the other pole. If the pressure of the rocker on the cylinder be regulated well, a very low sound is produced, specially when the rocker is an iron one. A copper rocker or a copper plate also gives good results. The cylinder was placed on a sounding-box.

An intermitting current sent through the microphone of Prof. Broun (NATURE, vol. xviii. p. 383), as also through a jar with gas cinders, gives a feeble though perfectly audible sound. By using a stronger current, I believe the sound would have been louder. My battery was of four Bunsen cells.

In my opinion the only possible explanation of these facts is the following:—The resistance at the places of contact being relatively very great, a good part of the heat generated by the current appears here, and by dilatations the lever of the Morse-key or the rocker is uplifted. During the interruptions of the current the heat is diffused, and the lever or the rocker falls back, to be again uplifted in the next period of closed current. In this way the lever or the rocker acquires an oscillation of the same period as that of the intermitting current. That a sufficient diffusion of heat in so short a time is possible may be seen from the Trevelyan experiment itself.

My conclusion is that the action of the microphone or of the jar with gas cinders as a receiver depends upon the varying dilatation at the points of contact by the varying intensity of the current. V. A. JULIUS

Power of Stupefying Spiders possessed by Wasps.—Mimicry in Birds

MR. CECIL'S remarks on the spider-hunting wasp (NATURE, vol. xvii. p. 381) have interested me greatly, these wasps being very common here. Two species are continually hovering about the wall-plates and eaves of my house in search of their prey, which they hunt out with most praiseworthy perseverance. Both are thin-bodied, but one is half as long again and has a larger body, as also broader black rings than the other. A few remarks may be of interest to your readers.

These wasps build variously-shaped mud nests, which are met with hanging from twigs in the bush or stuck on walls in houses and under overhanging rocks. Some species use a red sandy loam, others common mud.

The nest is divided into compartments, each of which contains an ovum, and is filled with spiders, on which the larvæ feed.

For a long time I was under the impression that these spiders were killed outright, and was puzzled to find them perfectly fresh and juicy after a lapse of a fortnight, with a thermometer ranging up to 118° in the shade; but a few days ago I broke open a large nest, and was astonished to notice a constant movement in the legs of half-a-dozen spiders which were contained in one cell.

I have since then examined several nests, and invariably with the same result.

Mrs. Hubbard's explanation of the tracking described by Mr. Cecil (NATURE, vol. xvii. p. 402) is no doubt correct as far as it goes, but the wasps here seem to "go in" for every and all species of spiders, with only one exception.

My house abounds with a podgy black spider having a bright vermilion patch on the medial line of the body and two bright spots above this patch. This insect is a most venomous and dangerous neighbour; its bite is highly poisonous and inflicts excruciating agony on the person or animal bitten. I have seen a terrier succumb to its effects in eight hours, and one young man went mad in 1868 from the effects of a bite received in the wrist. Several persons have been bitten here during the last two years, and only the immediate use of ammonia and spirits saved them from serious injury. This spider is carefully avoided by the wasp, who immediately retreats on discovering that the occupant of a web belongs to this species.

Several small hunting spiders are to be found in the wasps nests which do not seem to leave any line behind them, and whose mode of life is very nomadic. I quite believe from observation that wasps can and do run these insects down by scent, although it is difficult to obtain direct proof of the fact. They seem quite capable of discerning between their prey and enemies, as shown above; and granting this, it does not seem a great stretch to a further development of instinct having the propagation of the species in view.

Can any of your readers explain to me in what manner the spiders are stupefied and not killed?

I have lately noticed cases of protective mimicry in birds which I think are worth recording.

While following a small wood-swallow (*Artamus minor*) a few evenings back, they suddenly disappeared near a large leaning gum-tree. Walking up to the spot they suddenly flew out of the trunk, which I found had been hollowed out by fire, leaving the inside charred and black. The birds had chosen this black surface as their roost, and when followed in the day-time invariably flew into this refuge. It was impossible to detect the birds when clinging to the charred surface, with which their plumage matched.

Artamus albiventris, I find, in like manner chooses a greyish back as a roost against which they are less liable to be detected. *Erythrina vespertilio* is a favourite tree with this species.

I have on several occasions taken *Podargus giganteus* and other species alive by hand in broad daylight. These birds sit perfectly still on a limb of an iron-bark or acacia, whose bark resembles their plumage in colour. W. E. ARMIT

Georgetown, Queensland, July 19

Agricultural Ants

I HAVE lately discovered a colony of agricultural ants near Georgetown. The species is very small and red.

My attention was first directed to these tiny harvesters by noticing heaps of chaff and hulls in a bare spot situated in a grove of young acacia trees.

The formicaries are entirely subterranean, being entered by a funnel-shaped tube.

Roads diverge from this gate in four or five directions, and during working hours are alive with what appear like white insects, the little ants being covered by their load. Some of these ants seem to clean the grain and carry out the husks, which form a heap round the opening to the nest. The clear space round each opening is small, certainly not more than eighteen inches in circumference, and a small mound not more than six inches in height is formed with the earth excavated in forming the nest. The only species of grain harvested is the seed of *Perotis rara*, whch is light when quite ripe. I cannot give the generic name of these little fellows, never having devoted any special study to the family, but shall be happy to furnish specimens in spirits to any naturalist who will forward his address. WILLIAM E. ARMIT

Dunrobin, Georgetown, July 19

Meteor

AT about 5.50 P.M. to-day I saw a most brilliant meteor fall quite close to the moon, which was shining brightly at the time: it was in full daylight, shortly after the sun had gone down. Its direction was nearly perpendicular, but inclined a little from north to south as it fell. It was of a bright green colour; its motion rapid, its path long, and the time during which it was visible about two seconds, and it left no visible trace behind it.

JANSSEN'S NEW METHOD OF SOLAR PHOTOGRAPHY

IN two papers published respectively in the *Comptes Rendus* for December, 1877, and in the *Annuaire* of the *Bureau des Longitudes* for the current year, M. Janssen has described a new method of photographing the solar disc, which he has successfully carried out at the Meudon Observatory, during the past twelve months; and he has also drawn attention to some striking features in the constitution of the photosphere, disclosed for the first time in the beautiful pictures which are among the first results of his process. These may be regarded as only the forerunners of further important discoveries. Through the courteous liberality of M. Janssen, I have lately had the advantage of studying the process in the Meudon Observatory, and a description of its distinctive features, and a brief notice of such of the results as M. Janssen has already published, will certainly be acceptable to many who are interested in the recent developments of solar physics, and have not ready access to the original papers.[1]

M. Janssen's pictures of the solar disc are distinguished from all those previously obtained with the photoheliograph, not only by their great size (30·5 ctm. diameter), but more especially by the remarkable sharpness and definition with which they display the details of photospheric structure, which are such that, for the purpose of their more effective study, it is found advantageous to enlarge the original pictures to three and even nine times their original linear dimensions. The greatly extended means of research which M. Janssen's invention places in the hands of the solar physicist will be obvious, when we consider the difficulties which attend any prolonged ocular inspection of the solar disc, hitherto the only practicable method of examining its detailed structure. "In spite of the interposition of coloured glasses, helioscopes, &c., the eye must seize on the details in a dazzling field, and perform its functions under conditions which are quite unfamiliar. The true variations of luminous intensity in different parts of the image can no longer be appreciated, and the impressions produced do not correspond to reality. Thus may be explained the diversity of the opinions which have been put forward respecting the forms and dimensions of the granulations, and of the constituent parts of the solar surface"—diversities well illustrated by the old controversy of the "willow-leaf" and "rice-grain" bodies in the photosphere. In M. Janssen's pictures the forms, sizes, and arrangement of the bodies described under these appellations are exhibited in the most satisfactory manner, and as, in a favourable state of the atmosphere, the pictures may be repeated at as short intervals as the operator pleases, the movements and changes of form exhibited by these bodies may be studied with the utmost ease in a register which preserves the most fugitive phases of their appearance, and is available for leisurely re-examination at any future time.

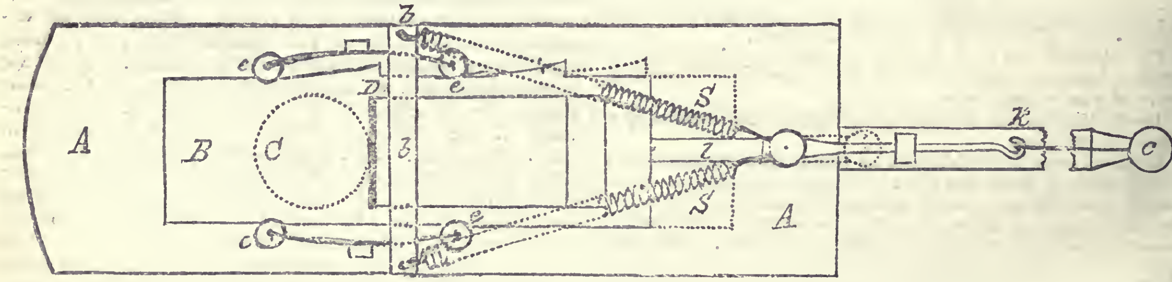
Before noticing the novel facts which M. Janssen has thus brought to light, I will briefly describe the principles of the process itself. The main difficulty to be surmounted in order to obtain a sharply defined photographic picture of the details of the solar disc is presented by the phenomenon known as photographic irradiation, in virtue of which a brilliantly illuminated surface occupies, on the negative picture, a proportionally exaggerated space; its borders being extended over the darker objects around. This phenomenon, M. Janssen remarks, "is very striking in all the photographs of total eclipses which have been obtained since 1860, which exhibit the images of the protuberances encroaching on the lunar disc, to the extent, in some cases, of ten and twenty seconds of arc, and even more." The granulations (to employ M. Janssen's terminology) visible on the solar disc have a mean diameter of not more than one second of arc, and in ordinary photoheliograms their very existence is therefore completely masked by irradiation.

[1] The present notice contains a more detailed description of the process than M. Janssen's original papers, and is published with his full approval and authority. With characteristic liberality M. Janssen writes:—"Quant au procédé lui-même, il est evident que toute personne un peu au courant de la photographie astronomique pourra l'appliquer et obtenir bientôt des photographies semblables à celles que nous obtenons. Je serai aussi très probablement devancé sur plusieurs points de la constitution du soleil que ces procédés peuvent révéler. L'inconvenient n'est que pour moi, et je crois qu'il vaut mieux dès aujourd'hui livrer la méthode au public scientifique. Les progrès de la science y gagneront certainement."

The simple and beautiful contrivance by which M. Janssen has succeeded in getting rid of irradiation, is to restrict the photographic action to one small sheaf of rays of the spectrum, viz., those which extend from the line G a short distance towards H. In a series of experimental photographs of the spectrum which M. Janssen took in my presence (with calc-spar prisms and a rock-crystal lens) and in which the time of exposure was varied successively from two-thirds of a second to three minutes, those obtained with the shortest exposure represented only that part of the spectrum immediately contiguous to G and extending a short distance towards H; and in this, the spectral lines were exhibited with extreme sharpness. With a more prolonged exposure the range of the image was greatly extended in both directions, accompanied by intensified action in the G–H region, which impaired the local definition.[1] Taking advantage of this fact, in the new process, the collodionised plate is exposed to the sun's action only so long as to allow of the action of the most actively photographic rays, and this is the cardinal condition of success. In practice, the duration of the exposure is restricted to between $\frac{1}{2000}$ and $\frac{1}{3000}$ of a second, in summer, being varied according to the season and to the time of day. The means by which this delicate adjustment is effected and verified will be described presently.

A second condition is, so to adjust the distance of the sensitised surface from the lens of the instrument, that it shall exactly coincide with the focus of the G rays. The necessity of this precaution will be readily understood when it is borne in mind that no lens is perfectly achromatic, and that, in virtue of the first condition, the rays in the vicinity of G alone produce the image. The remaining conditions are, the adoption of as large a plate as can be readily manipulated and some improvements in the process of preparing and developing the plates, whereby a very perfect surface is insured for the reception of the image, and a graduated development after exposure.[1]

The photoheliograph employed was constructed specially for the Meudon Observatory by M. Prazmouski of Paris. It has an object-glass of five inches diameter, and a reversing ocular, giving an erect image on the sensitized plate. The finding telescope casts an image on a disk of ground glass; by observing which, the operator can judge the exact instant for releasing the sliding screen, which causes the instantaneous exposure of the sensitised plate. At present, the position of the telescope is adjusted by means of winches worked by hand. The construction of the sliding screen, on the accurate adjustment and working of which the success of the operation mainly depends, will be understood on reference to the accompanying rough diagram (which, however, is not drawn to scale, and in which, to avoid confusion, some of the minor details are omitted). A A is an oblong brass plate which serves as a frame for the mechanism, and is introduced through a slit in the side of the telescope, exactly at the spot where the real image is formed by the object-glass. At the spot where the image falls, the plate is pierced with a circular aperture somewhat larger than



the image, shown by the dotted circle C. But this is completely covered by the sliding screen B, excepting such portion as is momentarily uncovered by the transverse slit D, in its passage across the image. The width of the sl t D can be varied by means of a micrometer screw, which is omitted in the diagram. The sliding screen works between four small grooved wheels *e e*, fixed to curved springs, which press them against the edges of the screen-plate; and one of these edges is shaped in the manner shown in the diagram, so that the pressure is increased from the instant at which the slit D reaches the margin of the circular aperture C, neutralising the acceleration of the movement by the continued action of the springs, and rendering it uniform during the passage of the slit across the image.[2] Thus the image is allowed to fall on the sensitised plate, not as a whole, but in successive slices, and the width of the slit is so adjusted to the rate of motion, that each slice is exposed during from $\frac{1}{2000}$ to $\frac{1}{3000}$ of a second only. The motion of the screen is effected by three spiral springs, two of which S S, are shown in the diagram (the central spring being omitted). The fixed ends are attached to a bar *b b* screwed to the slide A A; the free ends to a stud on the bar *l* which projects from the proximal end of B, is bent twice at right-angles and terminates in the hook *k*. In setting the screen before operating, a loop of twine is passed over the hook, which is then drawn towards the clip *c*, extending the springs S S, and bringing the screen into the position shown by a dotted line on the diagram. The twine is made fast in the clip *c* and all is in readiness for the operation. At the critical moment, the retaining string is cut and the slit D is rapidly drawn by the tension of the springs across the field, till checked by a stop not shown in the diagram. The movement of the screen is generally horizontal, but a gravity compensation is attached which can be employed when the movement is vertical.

The rate of the movement and the uniformity of the motion are determined by attaching, by means of wax to any part of the sliding screen, a glass slip coated with lamp-black. A tuning fork with an attached bristle, being made to vibrate transversely to the movement of the screen, the latter is released as in the actual operation of photographing, and the length of the wave marked by the bristle on the carbonised surface, multiplied by the width of the slit D, and divided by the number of vibrations of the fork per second, gives the duration of the exposure; while the uniformity of the movement is tested by the equality of the wave-lengths, which correspond to the passage of the slit D across the circular aperture C. By this means, the uniformity of exposure can be regulated to $\frac{1}{10000}$ of a second.

In order to obtain the exact position of the sun's axis on the plate, the instant of the exposure is noted by the

[1] Owing probably to spherical aberration.

[2] This, M. Janssen suggests, may be otherwise effected by an arrangement which will arrest the action of the springs at the instant when the slit reaches the margin of C.

[1] In this part of the process, M. Janssen acknowledges the assistance of M. Arents, to whom the writer is also indebted for much information.

chronometer, and the exact level of the slide containing the sensitized plate is observed with an accurate clinometer before removing it from the camera.

As M. Janssen has pointed out, the chemical preparation and development of the plate require very great care, in order to obtain the requisite sharpness of detail. The gun-cotton for the collodion is prepared at a high temperature (70° C.), and numerous precautions are taken to ensure that the collodion film shall be perfectly even, and free from the smallest speck of foreign matter. The image is developed gradually, beginning with a solution of ferrous sulphate, and after thorough washing, completing with a solution of pyrogallic acid, after which the image is strengthened with a mixture of pyrogallic and silver nitrate solutions.

In a favourable state of the atmosphere, the pictures thus obtained leave nothing to be desired in point of sharpness and definition of detail. But, as a matter of course, all states of the atmosphere do not permit of equal success, the process being subject to the same atmospheric contingencies as in all astronomical work with the telescope. The best results were obtained in the late autumn, and during this last spring.

The character of the photospheric surface as displayed in the new photographs, will be best described in a translation of M. Janssen's own words: "The photographs show that the solar surface is covered everywhere with a fine granulation. The forms, dimensions, and arrangement of the granular elements are very varied. Their size varies from some tenths of a second to three or four seconds. The shapes are circular or elliptical, and more or less elongated; but often these regular forms are more or less distorted. The granulation is exhibited everywhere; and, at first sight, it does not appear to present a different constitution towards the polar regions. But this is a point to be further investigated. The illuminating power of the granular elements, taken separately, varies much; they appear to be situated at different depths in the photospheric layer. The most luminous of them, those which more especially contribute to the luminosity of the photosphere, occupy but a small fraction of the surface of the sun.

"But the most remarkable result yet obtained, and which is exclusively due to the employment of the photographic method, is the discovery of the photospheric network (*réseau photosphérique*). An attentive examination of the photographs shows that the photosphere has not an uniform structure throughout, but is divided into a series of figures, more or less distant from one another, and exhibiting a special constitution. These figures generally have rounded contours, but also often rectilinear and sometimes polygonal. Their dimensions are very variable, and they sometimes attain to a minute or more in diameter. While, in the intervals between these figures, the grains are distinct and definitely bounded, although of very variable size; in their interior, the granules are half obliterated, drawn out and confused; most frequently, indeed, they have disappeared, giving place to trains of matter which replace the granulations. Everything indicates that, in these spaces, the photospheric substance is subject to violent movements which have confounded the granular elements. . . . This fact enlightens us as to the forms taken by solar activity, and shows that this activity is always very great in the photosphere, even though there be no spot visible on the surface. I will further draw attention to this very important fact, of which very distinct evidence is furnished by certain photographs, viz., that numerous very dark points appear in the regularly granulated tracts, indicating that the photospheric layer can have but a very small thickness."

In another paper, Mr. Janssen deduces some further conclusions of interest. He observes:—

"If the solar layer which forms the photosphere were in a state of repose and perfect equilibrium, it would result from the fact of its fluidity, that it would form a continuous envelope around the solar nucleus. The granular elements would be confounded together, and the lustre of the sun would be uniform in all its parts. But the ascending gaseous currents do not admit of this state of perfect equilibrium. They break up and divide the fluid layer, escaping at a great number of points. Hence results the formation of the granular elements, which are but so many fractions of the photospheric envelope, and which tend to take a spherical form, in virtue of the gravity of their constituent parts. . . . But even this state of equilibrium of the individual parts is but rarely realised; in numerous points, the currents drag along with them the granular elements, and these latter lose their spherical form, and eventually become no longer recognisable where the movements are most violent. . . . Moreover, in the regions of relative calm, the movements of the photospheric medium do not allow the granular elements to arrange themselves in an even layer, whence results the greater or less immersion of the grains beneath the surface, and consequently, owing to the great absorptive action of the medium, the great differences of their lustre shown in the photographic pictures. . . . We may further conclude, from the fact of the relative rarity of the most luminous grains in the photographs, that the illuminating power of the sun is due principally to that of a small number of points on his surface. In other words, if the solar surface were completely covered with granular elements of equal brilliancy with these, its illuminating power, according to a first approximate estimate, would be from ten to twenty times greater than it is." It will be interesting to ascertain, at the next epoch of sun-spot maximum, whether the brilliant granules occupy a relatively larger proportion of the solar disc than at the present time. The direct evidence which such an observation will afford on the important question of the periodic variation of solar radiative intensity, a question on which much diversity of opinion still exists, will be of the highest value.

H. F. BLANFORD

BIOLOGICAL NOTES

THE ANATOMY AND AFFINITIES OF THE AYE-AYE.—Dr. Alix having recently dissected a young male Aye-aye (*Chiromys Madagascariensis*), communicates, through Prof. Gervais, to the Academy of Sciences of Paris (*Comptes Rendus*, July 29, p. 219), some notes on certain points in its anatomy which bear upon the much-vexed question of the position of this curious animal in the mammalian series. It seems that his observations confirm in all points the opinion of all those eminent naturalists who, in accordance with De Blainville, and contrary to Gmelin and Cuvier, have held that the Aye-aye must be approximated to the lemurs and separated from the rodents, fresh facts being brought forward in support of this view. First, as regards its myology. The extensor communis hallucis, which in rodents is attached to the outer condyle of the femur, arises in the Aye-aye from the tibia. The biceps brachialis, which has only one head in the majority of rodents, has two in the Aye-aye. The supinator longus, which is generally absent in the rodents, has in the Aye-aye a good development. The common extensor of the digits, to those of the hand or foot, is composed of two distinct fascicles, of which one furnishes the tendons of the second and third digits, the other those of the fourth and fifth, from which it results that the Aye-aye, like the other Lemurina, possesses a paired digital system, and resembles in this feature the cloven-hoofed Pachyderms and the Ruminants, while the other mammals have, under all relations, an unpaired digital system. Dr. Alix has, moreover, verified the presence of a rotator muscle of the fibula, previously men-

tioned by Dr. Murie and Mr. Mivart in their paper upon the anatomy of the Aye-aye, published in the *Proceedings* of the Zoological Society. In examining the nervous system of the cervical region arrangements were discovered quite different from those seen in rodents. For example, the trunk of the great sympathetic nerve, which is otherwise separated from the pneumogastric in the whole extent of this region, has no middle cervical ganglion, but only an inferior one, excessively reduced in bulk. The superior cervical ganglion, situated immediately above the bifurcation of the common carotid, adheres by its fibrous sheath to the pneumogastric; and it is at this spot that the superior laryngeal nerve detaches itself from the pneumogastric, crossing the ganglion with which it enters into connection. On the left side there is no indication of a nervous filament answering to a depressor nerve, while on the right there may be seen to detach themselves from the superior laryngeal nerve two filaments of excessive tenuity which go to rejoin the trunk of the great sympathetic nerve. Nothing in this arrangement suggests resemblance to the nervous cord so distinct among the rodents, and above all among the Leporidæ, which, from this very circumstance, have furnished physiologists with the opportunity of making experiments of the greatest value. This character distinguishes the Aye-aye also from the opossums, which were placed by Illiger with the apes and lemurs in his order "Pollicata." The nervous arrangements, in short, confirm the results arrived at by the study of the muscles, viscera, and organs of generation, of the external form, skeleton, and dentition. J. C. G.

PROF. CARUEL'S CLASSIFICATION OF THE VEGETABLE KINGDOM.—At the close of his recent work, "La Morfologia Vegetale," Prof. Caruel of Pisa proposes a classification of the vegetable kingdom which has not so much of novelty in its principles of classification as in its terminology and the salient characters of the groups. He makes the following five primary groups, viz.:—1. PHANEROGAMIA. Every individual is trimorphic. The first form is neutral, and is capable of indefinite development, and of organic reproduction, principally by means of buds. This organic form gives rise, through the medium of the flower, to the two other (sexual) forms, male and female, which have only a definite development. The male form or pollen is thalloid; the female form or gemmule (ovule) is cormoid; this last produces, first, a pro-embryo as the result of the fecundation by the fovilla of the pollen, of an oosphere contained in a closed oogonium, and finally, the embryo of the neutral form, which develops at the extremity of the pro-embryo and in the same direction. In the subdivision of Phanerogamia, Caruel discards the distinction between Gymnospermia and Angiospermia, retaining, as the two primary classes, Monocotyledones and Dicotyledones, and giving the higher rank to the former. 2. SCHISTOGAMIA, including Characeæ only. These are also trimorphic; but the male sexual form consists of vermiform phytozoa (antherozoids) instead of pollen-grains, formed in an antherocyst (antheridium) differing in structure from the anther; the female form consists of an oogemma (archegonium) comparable to a gemmule, but naked; the neutral form springs directly from the oospore, which, on germinating, produces the embryo transversely. 3. PROTHALLOGAMIA, or Vascular Cryptogams. These are also trimorphic The neutral form does not produce the two sexual forms, but spores; these, on germinating, are transformed into sexual prothallia, with archegonia and naked oospheres, and vermiform phytozoa contained in antheridia; the oospore gives rise transversely to the embryo of the neutral form. The Prothallogamia are divided into Heterosporæ and Isosporæ. 4. BRYOGAMIA (synonymous with Muscineæ). The distinguishing character of this group is the indefinite power of development of the female individual, together with the definite development of the neutral form or sporogonium. A consequence of this is the continued and repeated fecundation of which the female form is capable, which distinguishes the Bryogamia from the three preceding groups. The embryo springs directly from the oospore; the male forms are phytozoa. The group is divided into Musci and Hepaticæ. 5. GYMNOGAMIA (Thallophyta or Cellular Cryptogams). The simplest Gymnogamia possess only a single form, which is reproduced agamically by fission, by conidia and sporidia, or by gamogenesis, but without any sexual differentiation. In others there is sexual differentiation into male and female forms; a few have also a third neutral form, when the oospore produces zoospores, instead of passing directly into the female form. They resemble the Bryogamia in the definite development of the neutral form and the indefinite development of the female form, but differ in the zoospore-like form of the phytozoa, and in the structure of the oogonium, which is isolated and naked, and does not form part of an archegonium. Prof. Caruel altogether discards the old classification of Thallophytes into Algæ, Fungi, and Lichens, but does not propose any other in its place, thinking it probable that, as our knowledge of some of its forms increases, it will be broken up into several primary groups He thinks it would be an advantage if the term Cryptogamia were altogether disused.

TRANSITION FORMS OF CRINOIDS IN AMERICAN PALÆOZOIC ROCKS.—Messrs. C. Wachsmuth and F. Springer have carefully studied the crinoids of the subcarboniferous rocks of the Mississippi valley, especially the Burlington and Keokuk limestones. There is probably no region in the world which exhibits, within the same limited geographical extent, so great and uninterrupted a range of crinoidal deposits in geological succession, almost unaltered. These observers conclude that extravagant forms and developments are not perpetuated, and that types mostly cease to exist when they reach a culmination in anatomical features. A large proportion of the genera become extinct in the formations above mentioned. The extinction of specific forms was not coincident with the close of the respective epochs of limestone deposits, but most of the changes were made by a series of slow and gradual modifications of specific characters, which correspond in a striking manner with the changes in individual life by growth. The smaller and less conspicuous forms were generally persistent, and ranged through the whole crinoidal formations with comparatively little change.

GEOGRAPHICAL NOTES

ACCORDING to present arrangements, we believe that Mr. Keith Johnston, the leader of the expedition which the Committee of the African Exploration Fund are about to despatch from the East Coast of Africa to Lake Nyassa, will leave England on November 14 for Zanzibar, together with his second in command, Mr. Thomson, whose more especial function it will be to study the geology of the country traversed. Mr. Thomson, we believe, has had an excellent training as a geologist, and it is expected that he will make important contributions to our knowledge of the geology of the region to be visited. The expedition will not actually start for the interior till next spring, and the interval will no doubt be utilised in making short journeys on the mainland, and in procuring all information possible in regard to the inhabitants, language, &c., of the region which is about to be thoroughly and scientifically explored. We sincerely trust that Mr. Johnston may not meet with the same trouble in the matter of porters as has so long retarded the progress of the Belgian and one or two other expeditions, but we do not hear that the Royal Geographical Society have formally given in their adhesion to the most recent

suggestion for facilitating African travel by the purchase of one or more Indian elephants.

THE *Moniteur Belge*, of October 12, publishes late intelligence respecting the International Association's East African Expedition, gathered from communications dated Zanzibar, September 17. The seventy-one porters engaged by M. Greffulhe were at Bigviro on August 22, and 200 others had been collected through the exertions of Père Etienne, Superior of the Mission at Bagamoyo. It was expected that they would have joined M. Wautier at Mwoméro on September 18. The *personnel* of the expedition is, therefore, now complete, and the travellers will have started by this time to rejoin M. Cambier with the baggage abandoned by the deserters. We further learn that Dr. Dutrieux wrote from Mpwapwa on August 26 to M. Greffulhe, stating that M. Cambier was pursuing his journey and was then at Kididimo, about 400 kilometres from the coast. His letter reached Zanzibar on September 4, and since then no fresh news has been received of the movements of the members of the expedition. There seems to be no truth in the rumour that the members of the Belgian expedition have been assassinated.

THE Dutch vessel *William Barends* has returned to Amsterdam from her voyage to the Arctic regions. It is stated that the voyage has been very successful from a scientific point of view, and it is expected that a full account of the discoveries made will shortly be published.

PETERMANN'S *Mittheilungen* contains an article on Turkey as it stands according to the Berlin Treaty, with a map. Dr. Emin Effendi's narrative of his journey in the African Lake Region is concluded, and an accompanying map shows the present position of the question as to the Muta Nzige, according to the data furnished by recent explorers. The south end of the Albert Nyanza lies to the north of 1° N. lat., and to the south is another Muta Nzige, of which Stanley's Beatrice Gulf is a southern extension. The Victoria Nile, between 1° and 2° N., and on the 33rd degree of E. long., broadens out into two lakelets, Gitansege and Codscha. Herr Kanitz contributes an interesting geological and physical paper on the Balkans. Perhaps the most interesting paper is one by Prof. H. Fritz on the periodical changes in the length of glaciers. The author has collected a large number of historical data to prove that there has been something like regularity in the changes of the Alpine glaciers. Important factors in seeking for the causes of change in the length of glaciers are temperature, snowfall, atmospheric moisture, clouds, direction of the wind, and atmospheric pressure. Prof. Fritz seems also of opinion that a connection may be traced between sun-spots and changes in the length of glaciers. The subject is of importance in various directions, and we trust that Prof. Fritz will continue the observations which he has so well begun.

RECENT advices, up to the beginning of September, have been received from Prof. Hayden, in the geyser regions of the Yellowstone, where the work of the survey was being prosecuted with great energy. Shoshone has been thoroughly mapped and explored, and the mammoth hot spring was next to be visited. Mr. Jackson has made large numbers of superb photographs of the geysers and other points of interest. Investigations into the temperature, composition, and other features of the hot springs are being carefully made, and a map is in progress on the scale of one inch to the mile. The survey of Point of Rocks, on the Union Pacific Railroad, along the west side of the Wind River Mountain, will next be attempted; thence he will proceed by Snake River on the east side of the Teton range to the sources of the Snake River. Dr. Hayden expected, after spending the month of September in the Park, to return along the east side of the Wind River Mountains *viâ* Camp Brown to Rawlins, on the Union Pacific Railroad, thence to Cheynene, which point it was hoped to reach on October 20.

WE have already noticed from time to time the movements of Mr. F. A. Ober, who has been engaged for two years under the auspices of the Smithsonian Institution in exploring the natural history of the West Indian Islands. His researches relate more particularly to the birds, his object being to secure the typical forms of all the islands, so that the West Indian fauna can be studied as a whole, his attention not being confined to one or two only of the islands. He has been extremely successful in his work, and has sent in numerous collections of much interest, embracing many new species, together with quite a series known previously by single specimens only. Last advices were dated Martinique, August 18. He expected to start for Guadeloupe on August 20, and to proceed thence to Marie Galant.

DR. E. TIETZE has just published in the *Jahrbuch* of the Vienna Geological Society an important paper on Mount Demavend, with a map of the mountains of the surrounding region. Demavend, according to the author, is a volcano in the solfatara condition, whose activity has waned within the memory of man. Its highest point, which even now gives out hot gases, contains a small crater, and stands inside the ruins of an older crater wall of larger diameter.

WE have received the first volume of Dr. Lenz's account of his explorations in West Africa. The second volume will appear in the beginning of next year, and Dr. Lenz hopes to publish during the present winter the geological results of his African travels, with a geological map of Guinea, and several plates of fossils.

WE have received from Mr. Stanford two new maps bearing on the present political difficulties in Asia: one is a map of "The Indian and Afghan Frontiers," the other, "A map of Western Asia." In the former the physical features are boldly drawn; here we may see how the present political boundary of India, having already passed beyond the broad and unbridged Indus, has yet stopped short of the next natural frontier, ending apparently at the foot of the mountains, but nowhere in particular. And what mountains! Commencing at the southern extremity of the map with the modest elevation of 5,390 feet, they stretch northwards at an ever-increasing altitude, until at the northern extremity we read 18,900 feet. The marking of many altitudes is a commendable feature in this map. The political colouring is somewhat startling; we did not expect to find that there is so broad an interval generally between the Indian and Afghan frontiers; they appear to be coterminous only at Thul in the Kuram Valley. The other map embraces, as its name implies, a much wider area, and shows by colour the latest extension of the Russian frontier in the direction of the mountains of Central Asia. As the British frontier has advanced to the foot-hills on the southern side of this great mountain mass, so the Russian frontier has advanced, or is rapidly advancing, to the northern foot-hills. This mass, with a breadth of about 200 miles, and an average elevation of more than 10,000 feet, with sundry passes of 12,000 and 13,000 feet, is all (!) that intervenes between the British and Russian frontiers. The new Indian frontier railways are correctly shown on these maps; with the exception of a break at Sakkur, on the Indus, and about 100 miles yet to make from Rawul Pindi to Peshawur, we have railway communication all along the landward frontiers of India, from Kurrachee to Calcutta.

NEWS from Munich states that Dr. Eugene Forel is about to start on a scientific exploring tour to New Granada.

ON THE NATURE OF VIBRATORY MOTIONS[1]

III.

Experiments by which Compound Sounds are analysed by viewing in a Rotating Mirror the Vibrations of König's Manometric Flames.

TAKE a piece of pine board, A, Fig. 15, 1 inch (25 millimetres) thick, $1\frac{1}{2}$ inch (38 millimetres) wide, and 9 inches (22·8 centimetres) long. One inch from its top bore with an inch centre-bit a shallow hole $\frac{1}{8}$ inch deep. Bore a like shallow hole in the block B, which is $\frac{3}{4}$ inch thick, $1\frac{1}{2}$ inch wide, and 2 inches (51 millimetres) long. Place a $\frac{1}{2}$-inch centre-bit in the centre of the shallow hole in A and bore with it a hole through the wood. Into this fit a glass or metal-tube, as shown at E. Bore a $\frac{3}{16}$-inch (5 millimetres) hole obliquely into the shallow hole in B, and into this fit the glass tube C. Then bore another $\frac{3}{16}$-inch hole directly into the shallow hole in B. Put a glass tube in a gas or spirit flame and heat it red-hot at a place about two inches from its end. Then draw the tube out at this place into a narrow neck. Make a cut with the edge of a file across this narrow neck, and the tube will readily snap asunder at this mark. Then heat a place on the tube in a flame, and here bend it into a right angle, as shown at D, Fig. 15. Now fit this tube into the hole just made, as shown at D. These tubes may be firmly and tightly fitted by wrapping their ends with paper coated with glue before they are forced into their holes.

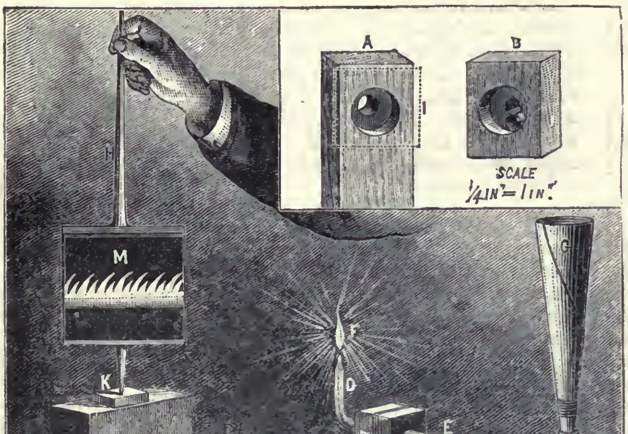


FIG. 15.

Get a small piece of the thinnest sheet rubber you can find, or a piece of thin linen paper, and, having rubbed glue on the board A around the shallow hole, stretch the thin rubber, or paper, over this hole and glue it there. Then rub glue on the block B, and place the shallow hole in this block directly over the shallow hole in A, and fasten B to A by wrapping twine around these blocks. Thus you will have made a little box divided into two compartments by a partition of thin rubber. Fasten the rod A to the side of a small board, so that it may stand upright.

Attach a piece of large-sized rubber tube to the glass tube E, and into the other end of the tube stick a cone, made by rolling up a piece of cardboard so as to form a cone 8 inches long and with a mouth 2 inches (51 millimetres) in diameter.

Now get a piece of wood 1 foot long, 4 inches wide, and $\frac{1}{4}$ inch thick. Out of this cut the square, with the two rods projecting from it, as shown at M. The lower of these rods is short, the one above the square is long. Cut the end of the shorter rod to a blunt point, and with this point make a very shallow pit in the piece of flat wood K for the rod and square to twirl in. Glue the piece of wood K on the end of a brick, L. Get two pieces of thin silvered glass, each 4 inches square, and, placing one on each side of the square M, fasten them there by winding twine around the top and bottom borders of the mirrors.

Experiment 16.—Through a rubber tube lead gas to C. It will go into the left-hand partition of the box and will come out at F, where you will light it. Now place the mirror-rod in the shallow pit in K, and hold the mirror upright so that you may see the flame F reflected from its centre.

Hold the rod upright and twirl it slowly between the thumb and forefinger, which should point downward and not horizontally, as shown in the figure. The flame appears in the mirror drawn out into a band of light with a smooth top-border. While twirling the mirror put the cone to your mouth and sing into it. The sonorous vibrations enter the side A of the box, and, striking on the thin rubber, force this in and out. When it goes in a puff of gas is driven out of the other partition, B, of the box, and the flame F jumps up. When the sheet of rubber vibrates outward it sucks the gas into the box B, and the flame F jumps down. Therefore, on singing into the funnel, you will see in the mirror the smooth top-border of the luminous band broken up into little tongues or teeth of flame, each tooth standing for one vibration of the voice on the rubber partition.

Place a lamp-chimney around the flame, should the wind from the twirling mirror agitate it, and be careful not to have the flame too high.

Experiment 17.—Another way of showing the vibrations of the flame is to burn the jet of gas at the end of a glass tube stuck into the end of a rubber tube attached to F. Now sling the tube round in a vertical circle, and you have an unbroken luminous ring; but as soon as you sing into the cone this ring breaks up into a circle of beads of light, or sometimes changes into a wreath of beautiful little luminous flowers, like forget-me-nots. To make this experiment you will be obliged to have a tube with a larger opening than that at F.

This instrument will afford you many an hour of instruction and amusement. We have only space to show you a few experiments. Others will suggest themselves whenever you use it.

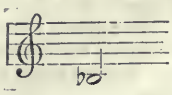
Experiment 18.—Sing into the funnel the sound of *oo* as in p*oo*l. After a few trials you will get a pure simple sound, and the flame will appear as in Fig. 16. Some voices get this figure more readily by singing E.

Experiment 19.—Twirling the mirror with the same velocity, gradually lower the pitch of the *oo* sound till your voice falls to its lower octave, when the flame will

[1] From a forthcoming work on "Sound: a Series of Simple, Entertaining, and Inexpensive Experiments in the Phenomena of Sound, for the Use of Students of every Age." By Alfred Marshall Mayer, Professor of Physics in the Stevens Institute of Technology. Communicated by the author. (Continued from p. 596.)

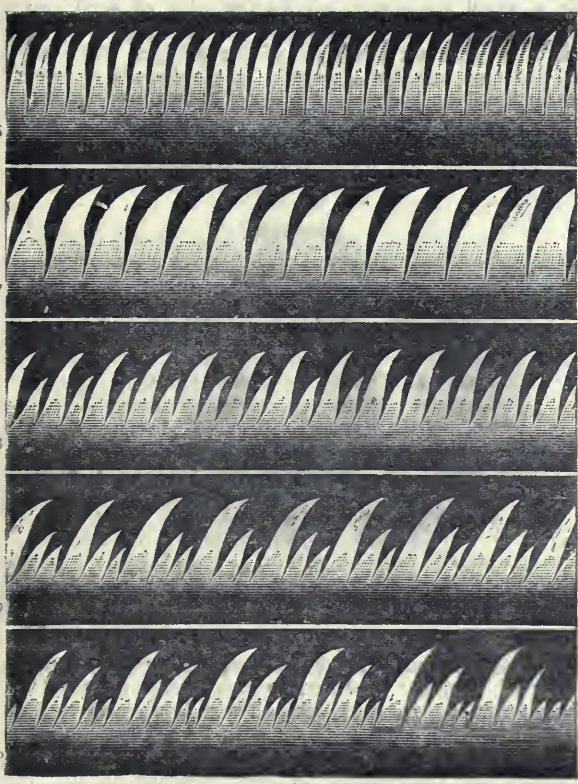
appear as in Fig. 17, with half the number of teeth in Fig. 16, because the lower octave of a sound is given by half the number of vibrations.

Experiment 20.—Sing the vowel-sound *o* on the note



and you will see Fig. 18 in the mirror. This evidently is not the figure that would have been made by a *simple* vibration. It shows that this *o* sound is compound, and formed of two simple sounds, one the octave of the other. The larger teeth are made by every alternate vibration of the higher simple sound acting with a vibration of the lower, and thus making the flame jump higher by their combined action on the membrane.

Experiment 21.—Fig. 19 appears on the mirror when we sing the English vowel *a* on the note f.



FIGS. 16, 17, 18, 19, 20.

Experiment 22.—Fig. 19 appears on the mirror when we sing the English vowel *a* on the note c.

Examine attentively Fig. 19. This shows that the English vowel *a* sung on f is made up of two combined simple vibrations. One of these alone would make the long tongues of flame, but with this simple vibration exists another of three times its frequency; that is, the vibration of greater frequency is the 3rd harmonic of the slower. As the slower vibration, making the long tongues of flame, is f, the higher must be c'' of the second octave above f. Each third vibration of this higher harmonic coincides with each vibration of f; hence each third tongue of flame is higher than the others.

Experiment 23.—In like manner the student must analyse Fig. 20 into its simple sonorous elements. Then he should, with the vibrating flame, examine the peculiarities of the various voices of his friends, and make neat and accurate drawings of the flames corresponding to them, so that he may analyse them at his leisure.

Experiment 24.—Blow your toy trumpet into the paper cone gently, and then strongly, and observe that the sound given by the trumpet is a complex one. Try if you cannot get a flame somewhat like the trumpet gives by singing *ah*, through your nose, into the cone.

The student will soon find that different persons, in singing the same note, as nearly alike as they can, will produce flames of very different forms. This is because the voices differ in the number and relative intensities of the simple sounds which form them.

Another cause of the different forms of flame obtained by different experimenters is due to the fact that they have used different lengths of tube leading from the cone to the membrane.

Experiment 25.—The fact can be readily shown by singing the same compound sound through different lengths of tube leading from the cone G to the membrane.

Terquem's Experiment, in which König's Flame is used instead of the Ear, and thus the Motions of a Vibrating Disk are made Visible.

The method of analysing the motions of a vibrating plate with the paper cone and tube applied to the ear, which has been used by us for a long time, has quite recently been adapted to M. König's flame by Prof. Terquem, of Lille, who has thus made these motions visible to the student, and has given us a charming experiment.

On how we Speak, and on the Talking Machines of Faber and Edison.—How we Speak.

The little musical instrument with which we sing and speak is formed of two flexible membranes stretched side by side across a short tubular box placed on the top of the windpipe. This box is made of plates of cartilage,

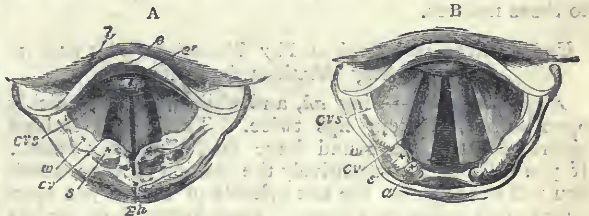


FIG. 21.

FIGS. A and B.—Views of the human larynx from above as actually seen by the aid of the instrument called the laryngoscope. Fig. A.—In the condition when voice is being produced. Fig. B.—At rest, when no voice is produced. *e*, epiglottis (foreshortened); *cv*, the vocal chords; *cvs*, the so-called false vocal chords, folds of mucous membrane lying above the real vocal chords; *a*, elevation caused by the arytenoid cartilages; *s*, *w*, elevations caused by small cartilages connected with the arytenoids; *l*, root of the tongue.

movable on each other, and bound together with muscles and membranes.

The top of the windpipe is formed of a large ring of cartilage, called the *cricoid* (ring-shaped) cartilage. Jointed to this is a broad plate of gristle, called the *thyroid* (shield-shaped) cartilage. This cartilage is bent into the shape of a V. The legs of this V straddle over the cricoid and are jointed to its outer sides. The peak of the V stands up and points toward the front of your throat. You can feel it, as it is the "Adam's apple." On the back of the upper edge of the cricoid ring are jointed two small pointed cartilages, known as the *arytenoid* (funnel-shaped) cartilages. Stretching from these to the inner sides of the legs of the V of the thyroid are two membranes, one to each leg. These are the *vocal chords.*

When the point of the thyroid is not pulled down these membranes are lax, and the breath from the windpipe passes freely between them and does not make them vibrate. (*See* B of Fig. 21.)

But when the peak of the thyroid is pulled down by

its muscles the vocal chords are stretched. At the same time the arytenoid cartilages move nearer each other, and the thin, sharply-cut edges of the vocal chords are brought parallel and quite close to each other, as is shown in A of Fig. 21. If the air is now forced through this narrow slit (called the *glottis*), the vocal chords vibrate just like the tongue in our toy trumpet, or like the reed in any reed-pipe. A puff of air passes between them; they separate; immediately afterward they come close together and the current of air is stopped. They again open, another puff goes into the cavity of the mouth, and then they close together again. Thus the glottis opens and closes with a frequency depending on the degree of stretch on the vocal chords.

Our experiments with König's flame have shown how composite are the sounds of the human voice. The quality of a voice depends on the number and relative intensities of the simple sounds which build it up.

SPEECH is voice modified and modulated by the movements of the parts of the cavity of the mouth, of the tongue, and lips.

The oral cavity is made larger or smaller, longer or shorter, and thus, resounding to some lower or higher harmonic of the voice, makes the others feebly heard.

Experiment 26.—If you form your speaking organs to say *o*, and then take your vibrating A-fork and hold it before your lips, you will hear the cavity of the mouth resounding to this sound. On changing the vocal organs to say *e* the resonance ceases.

All the vowel sounds are formed by a steady voice modified by the resonance of the different sizes and shapes given to the oral cavity.

The consonants are made by obstructions placed at the beginning or end of the oral sounds, by the movements of the tongue and lips; but, as this is a book of experiments, I leave you to inform yourself by experiments as to these matters.

Experiments in which a Toy Trumpet Talks and a Speaking Machine is Made.

Experiment 27.—Sing *ah*, and while doing so quickly open and shut your lips twice. These two sudden obstructions to the sound have made you say *mama*. If you will observe attentively the motion of your mouth you will see that for the last syllable of mama you open your mouth wider and keep it open longer than for the first syllable.

Experiment 28.—This is all we have to know to make our toy trumpet talk. You already have seen that its sounds,

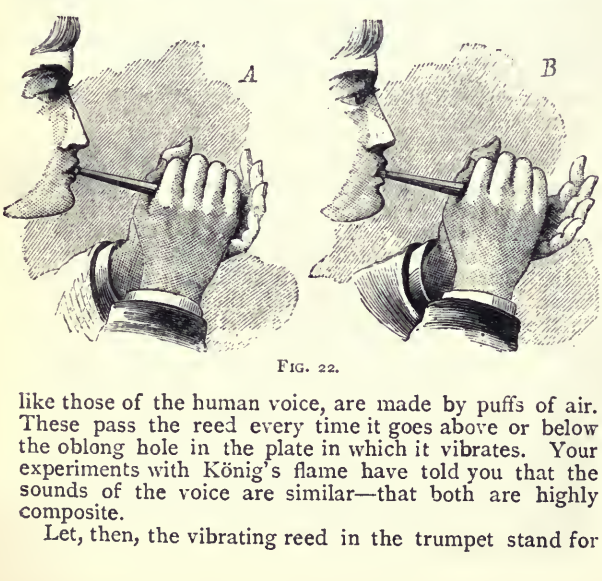

FIG. 22.

like those of the human voice, are made by puffs of air. These pass the reed every time it goes above or below the oblong hole in the plate in which it vibrates. Your experiments with König's flame have told you that the sounds of the voice are similar—that both are highly composite.

Let, then, the vibrating reed in the trumpet stand for your *vocal chords*. To get a resonant cavity like the *mouth* make one between your two hands, as shown in A of Fig. 22. The funnel of the trumpet is placed inside this cavity with the tube coming out in the crotch between the thumb and forefinger. The lips we will form of the fingers of one hand. By raising these together, more or less, from the other hand we can make a larger or smaller opening into the cavity between the palms of the hands, and thus get articulation.

Now blow into the trumpet as though you were speaking *mama* into it, so that you may make it sound twice, each sound lasting just as long as the sounds in mă and mā. While making the first sound, raise the fingers as high as is shown in A; while making the second, raise them as high as is shown in B. The trumpet talks and says *mama* quite plainly.

Experiment 28.—Let us make a talking machine. Get an orange with a thick skin and cut it in halves. With a sharp dinner-knife cut and scrape out its soft inside. You have thus made two hemispherical cups. Cut a small semicircle out of the edge of each cup. Place these over each other, and you have a hole for the tube of the trumpet to go out of the orange. Now sew the two cups together, except a length directly opposite the trumpet, for here are the *lips*. A pea-nut makes a good enough nose for a baby, and black beans make "perfectly lovely" eyes. Take the baby's cap and place it on the orange, and try if you can make it say

FIG. 23.

Faber's Talking Machine.

These simple experiments show the principles followed in the construction of the celebrated talking machine of Faber of Vienna. A vibrating ivory reed, of variable pitch, forms its vocal chords. There is an oral cavity whose size and shape can be rapidly changed by depressing the keys on a key-board. Rubber, tongue, and lips make the consonants. A little windmill turning in its throat rolls the *r*, and a tube is attached to its nose when it speaks French. This is the anatomy of this really wonderful piece of mechanism.

ELECTRIC LIGHTING

ALL the papers are still much occupied with correspondence about the electric light, the extent to which it may be brought into public use, and its possible effect upon the use of gas and upon gas companies. Many writers display much ignorance both as to the scientific and economical bearings of the matter; the most important communication on the subject that has appeared is the letter from Dr. C. W. Siemens in the *Times* of the 12th inst. Dr. Siemens writes as follows :—

The intelligence flashed through the Atlantic cable a few days since to the effect that Mr. Edison, the ingenious inventor of the phonograph, &c., had succeeded in dividing electric currents

indefinitely, for the distribution of light and power appears to have taken the public by surprise, and has exercised a most depressing influence upon the holders of gas shares. Having given close attention to the question of electric lighting ever since 1867—when, following the researches of my brother, Dr. Werner Siemens, I presented a paper to the Royal Society describing the dynamo-electric principle—I may be allowed perhaps to make a few remarks upon the novelty and probable effect of Mr. Edison's startling announcement.

In passing an electric circuit from a main conductor into several or any number of branches, the current divides itself between those branches, according to the well-known law of Ohm, in the exact inverse ratio of the electrical resistance presented by each branch. A current may thus be divided, for instance, into ten separate currents of precisely equal force, if each branch is made to consist of a wire of the same length and conductivity; but if one of these wires was again to be slit into ten wires, presenting in the aggregate the same conductivity, each of these wires would only convey 100th part of the total current. In the same way one of the minor wires might again be subdivided into branches, each of which would convey an amount of electric current which would be accurately expressed by the relative resistance of the branch in question, divided by the total resistance of all the branches put together. It would thus seem that nothing could be more easy than to divide a powerful electric current among as many branches of varying relative importance as might be desired; but in the case of electric lighting a difficulty arises in consequence of the varying resistance of each electric light or candle, due to the necessarily somewhat varying distance of the carbon points from each other, upon which the length of the luminous arc depends. In order to work a number of lights upon different branches of the same current, it is necessary to furnish each branch with a regulator so contrived that an increase of current corresponding to too near an approach of the carbon points will produce automatically an increased resistance in that branch circuit, whereas an accidental increase in the distance between the carbon points of any lamp will cause the regulator to reduce the extraneous resistance of the circuit to a *minimum*. Such a mode of regulating currents was present in my mind when, in addressing the Iron and Steel Institute in March, 1877, I ventured to express my conviction that natural forces, such as represented by large waterfalls, could be utilised for the production of motive power and electric light, in towns at a distance even of thirty miles from such source, by means of a large electric conductor. This suggestion gave rise to a good deal of discussion and criticism, especially in the United States; but I replied to some of these criticisms in delivering one of the Science Lectures at Glasgow in March last, having already referred to the matter in a discussion that was held before the Institution of Civil Engineers on January 29 last. Having in the meantime perfected the regulator, I showed it in operation at the *soirée* of the Royal Society on June 19, and have only been waiting to get experimental data complete in order to bring the whole subject before one of the scientific bodies. The arrangement may be said to consist simply of a thin strip of copper or silver, say six inches long and half an inch broad, stretched horizontally between two supports with a weight or spring exerting a certain pressure in the middle. The branch current to be regulated is passed through this strip of metal, which is thereby heated to a certain moderate extent, depending upon the amount of current passing, and upon the rate of radiation of the heat produced in the strip to surrounding objects. Suppose that when the normal condition of things obtains, the strip of metal is maintained at the temperature of, say, 100° Fahrenheit, and suppose that by an accidental approach of the carbons of a lamp the resistance of the circuit is suddenly decreased, an almost instantaneous increase of temperature of the thin strip will ensue, which will cause it to elongate slightly, and allow the weight resting in the middle to descend, which in its turn causes an increase in the resistance of a small rheostat, through which the branch current in question has to flow.

It will thus be seen that it is not so much the novelty of the announcement made by Mr. Edison as the manner in which it has been conveyed to us that has alarmed a portion of the British public, and I hold that such startling announcements as these should be deprecated, as being unworthy of science and mischievous to its true progress.

Although I am strongly of opinion that electricity will gradually replace gas in many of its most important applications as being both cheaper and more brilliant, I still hold the opinion, quoted by Mr. Northover in his letter to you of yesterday, that its application will be limited, at least during our generation, to such larger purposes as the lighting of our coasts, to naval and military signalling, to harbours, quays, warehouses, and public buildings, including perhaps picture galleries and drawing-rooms, where the objections to gas are already felt to the extent of banishing that means of lighting to the passages, offices, and bed-rooms. I am, however, of opinion that a revolution even to the extent indicated must be the work of time, and that while gas will undoubtedly in due course be supplanted by its more brilliant rival for the purposes just indicated, the consumption of gas will be maintained by the increasing area of application resulting from increase of towns, and by additional applications for cooking and for heating purposes, for which gas will supplant the use of solid fuel, and thus confer a new benefit upon mankind by doing away with the nuisance of smoke and ashes. If gas companies only rightly understood their interests they would themselves take up electric lighting for those purposes for which it has the decided preference, and at the same time promote the application of gas for heating, in doing which they would clearly increase their business as lighting companies, while benefiting the public by providing them with the very best sources of heat and light.

NOTES

AT the request of the Chemical Society Prof. Ad. Wurtz, of Paris, has accepted the office of Faraday lecturer for this year. The subject of his lecture is "La Constitution de la Matière à l'État gazeux." The lecture is to be delivered on Tuesday, November 12, in the Theatre of the Royal Institution, Albemarle Street. On the following day the Fellows of the Chemical Society propose entertaining Prof. Wurtz at a dinner to be held at Willis's Rooms.

THOSE interested in the progress of natural science at our old universities should take notice of the fact that, after considerable opposition of the "Board of Studies of the Natural Science School," the majority of that Board (chiefly by the aid of the examiners, who are London, and not Oxford, men) have carried a series of resolutions which provide that "candidates for honours in biology" may be examined in experimental physiology. The necessary encouragement to the study of this subject, viz., examination in it as an "honour subject" now existing, we may hope to see as the result some activity in the physiological laboratory of Magdalen College. Similarly we have to notice the recognition of the morphology and physiology of the vegetable kingdom as a necessary part of the study and examination of the Oxford student who is a candidate for "honours in biology." Botany was long resisted and sneered at in Oxford. External pressure has, however, reinstated botany in the Oxford school of natural science, and it rests with the examiners in future to maintain the study of this subject in the direction indicated by Sachs' admirable treatise on Botany published by the University press.

THE following changes are proposed to be made in the Council of the London Mathematical Society for the ensuing session:—Mr. C. W. Merrifield, F.R.S., to be president in the room of Lord Rayleigh, F.R.S., who is proposed for the office of vice-president in conjunction with Prof. Cayley, F.R.S.; Messrs. J. Hopkinson, F.R.S., and H. M. Taylor to be ordinary members of council in the room of Prof. Clerk Maxwell, F.R.S., and Mr. T. Cotterell. The valedictory presidential address will probably be delivered at the annual meeting (November 14).

THE new specimen of *Archæopteryx lithographicus* of Solenhofen, the discovery of which was announced some time back, has been purchased by Dr. Otto Folger, President of the Freie Deutsche Hochstift, for the sum of 35,000 marks (1,750*l.*), and

will no doubt be placed in the hands of some competent German palæontologist for description. It is said to be in several respects more perfect than the first, and hitherto unique, specimen in the British Museum, which has been the subject of the labours of Prof. Owen and Prof. Huxley on this most remarkable of extinct birds.

THE death is announced of M. Leymarie, Professor of Geology at Toulouse, and the author of the first geological map of France.

THE death, at the age of seventy, of Prof. William Monroe Davis, is announced as having taken place at Cleveland, Ohio, U.S., on July 21 last. When quite advanced in life Prof. Davis took up the study of astronomy, and has long been known as an original thinker and labourer in this field. After the resignation by Prof. Mitchell, as director of the Cincinnati Observatory, he was succeeded by Prof. Davis, who remained in charge for some considerable time. Of late years he has not been actively employed in any work, with the exception of the construction of a telescope, which has done excellent service in his hands.

THE Society of Arts announce that their opening meeting will be held on November 20, when the chairman's inaugural address will be delivered and the following medals presented :—The Albert Medal (gold), for "Distinguished Merit in Promoting Arts, Manufactures, or Commerce," to Sir William G. Armstrong, C.B., F.R.S., D.C.L. The council also announce that the following papers will be read :—On November 27, "The Land of Midian," by Capt. Burton; December 4, "The Electric Light," fully illustrated with experiments, by T. N. Shoolbred; December 11, "The Route to India, with especial Reference to the Euphrates Valley Railway," by Hyde Clarke; December 18, "Science Teaching in Elementary Schools," by Dr. Gladstone, F.R.S.; and the first course (six in number) of lectures by W. M. Williams on "The Manufacture of Mathematical Instruments."

A CORRESPONDENT makes the interesting suggestion that the microphone might be used to detect if insects have any audible means of communicating with each other, and if so, what is its nature in different classes of insects.

THE fourth annual conference of the Cryptogamic Society of Scotland was held in the Royal Botanic Garden, Edinburgh, on the 9th, 10th, and 11th inst., under the presidency of Prof. Balfour, and was a success in every way. The business meeting was held in the lecture-hall, and in addition to the president's address a number of papers were read relating to recent discoveries—both in species and in morphology—in cryptogamic botany. An excursion was made to the Penicuick woods, where about 170 species of fungi, including one or two new and several rare species, were noted. The public show was held in the winter garden and herbarium of the Royal Botanic Garden, and was visited by a great many people, who appeared to be much interested in the exhibition. A considerable number of hymenomycetes, &c., were arranged in classified order and named. Many distinguished botanists, both English and Scottish, attended the meeting, and were very hospitably entertained by the president and other members of the local committee. A notice of the scientific results of the conference will be given in the *Scottish Naturalist*. Next year's conference is to take place at Forres. Arrangements may be learnt from the secretary of the Society, Dr. Buchanan White, Perth.

MR. T. MUIR, M.A., of the High School, Glasgow, has forwarded to the London Mathematical Society a verification of Pervouchine's first result regarding the divisibility of $2^{2^{12}} + 1$ by $7 \cdot 2^{14} + 1$ (NATURE, vol. xviii. p. 104). The mode of verification will be understood from the following question and solution :—Is $11 \cdot 2^4 + 1$ a factor of any number of the form $2^m + 1$? $11 \cdot 2^4 + 1 = 2^7 + 2^6 + 2^4 + 1 = 10110001$ (radix 2). The question thus is—"Is there any number which when multiplied by 10110001 will produce a number of the form 1000...0001? Now knowing that the last digit of the multiplier and product is 1, we infer that the last digit of the multiplicand must be 1. Taking it as such and performing the multiplication we have—

    10110001
    --------
       .....1
     ....1000
    ....1
   ....0
  ....1
```

whence, in order that the result of the addition may be of the form ....0001, we see that the second, third, fourth, and fifth digits of the multiplicand must be 0, 0, 0, 1 respectively. Prefixing these to the first digit and continuing the multiplication we have—

```
      ....10001
       10110001
    -----------
      ....10001
   ....10001
  ....10001
 ..10001
 --------------
```

from which on addition we deduce other four digits of the multiplicand; and so on. When we have got in all twenty-two digits the figuring is as follows :—

```
       1011100100100001010001
                     10110001
    --------------------------
       1011100100100001010001
   1011100100100001010001
  1011100100100001010001
1011100100100001010001
------------------------------
```

and we find that addition then gives a product of the required form; and thus we have the result—

$$2^{29} + 1 \text{ is divisible by } 11 \cdot 2^4 + 1.$$

When there are few significant figures in the multiplier, as here, it will readily be seen that a very considerable lessening of labour is possible, that, in fact, the digits of the multiplicand can be written down at a steady pace without any auxiliary figuring at all. This is what was actually done in Mr. Muir's verification of Pervouchine's first case. With reference to the editorial query as to how the trial divisors came to be thought of Mr. Muir refers to the *Turin Transactions* for the present year, where there is a paper by M. E. Lucas, which almost entitles him to the merit of being a sharer in the discovery.

THE excavations made in Carniola under the direction of Herr von Hochstätter, on spots of palæontological and prehistoric interest, have hitherto been crowned with every success. The Kreuzberg Cave, near Laas, in the district of Zirknitz, proved to be an exceedingly interesting bear cave. The investigations made in this district, at St. Michael, near Adelsberg, and at Klenke, near Waatsch, have furnished undeniable proofs of the existence of prehistoric colonies and burial grounds at these places. Another interesting discovery has just been made at the Laibacher Moor, the well-known pile-dwelling ground. A peat digger found six silver coins of the size of a florin, which all bear the inscription of the Roman Emperor, Augustus Claudius. The discovery has been secured for scientific purposes.

THE Paris Academy of Arts has recently acquired an Egyptian papyrus which is particularly remarkable on account of its reputed age, which is estimated at over 4,000 years. It is perfectly preserved; its height is 8·30 metres, and its width 43 centimetres.

It contains a description of the death and the burial celebration of the mother of King Herod, from the first dynasty of Egyptian kings. The price paid by the Academy was 4,000 francs (160*l.*); the papyrus is now in the Exhibition.

IN the August number of the *Moniteur Scientifique* M. J. Laurent, of Marseilles, cautions the scientific world generally, and chemists in particular, against the use of de la Bastie's toughened glass. He considers the objects and utensils made of this substance to be no better than so many Prince Rupert's drops or Bologna flasks, from which they differ only by their shape. M. Laurent adduces an instance where a dish made of toughened glass was used at a stearine factory at Marseilles; it suddenly broke into thousands of fragments upon being placed on the metal scale of a balance. It was then in a state of cooling down from 110° C., at which temperature it had been maintained for some time; but it had previously been in use for about a month, and its sudden destruction was entirely inexplicable, save by the theory above mentioned.

WITH reference to Vesuvius the *Libertà* publishes the following letter from Prof. Palmieri, dated October 6:—"The phase of minor activity of the crater continues, nor is there sign of any speedy increase. Little smoke, very little lava, and a certain lesser activity in the eruptions of the new cone represent the phases of decreasing dynamism. According to some, I have announced augmenting force with the growth of the moon. I must state that I only said that if there was to be any increase, it would be verified towards the time of the full moon, according to the laws I have noted since Vesuvius has been my study, and confirmed by irrefutable documents from which I have drawn the history of our volcano. But, however it may be, this eruptive period, long foreseen, appears to require time to reach the evolution of the major phases it will ultimately attain." Telegrams from Naples on the 13th announced greatly increased activity in the volcanic action of Vesuvius.

MESSRS. MACMILLAN AND CO. have in preparation a textbook, systematic and practical, on the "Physiological Chemistry of Animal Bodies, and on the Changes which their Tissues and Fluids undergo in Disease," by Prof. Arthur Gamgee, M.D., F.R.S. The author seeks to fill up an important gap at present existing in English medical and scientific literature by preparing a succinct, though complete, account of the chemical processes of the organism, and of the methods of studying them. The work will primarily be a didactic and systematic treatise, and, though in no respect a servile imitation, will be constructedon the same plan as Prof. Kühne's most admirable, though now necessarily almost obsolete, "Lehrbuch der physiologischen Chemie:" Leipzig, 1866. It will differ, however, even in plan from that book, in containing elaborate descriptions of methods of research and directions for the performance of analyses, which will in part be introduced into the systematic portion of the text, and in part be added as appendices to each section. These appendices will be so detailed and complete as to render superfluous a separate laboratory treatise on Chemico-Physiological Analysis, such as the excellent books of Hoppe-Seyler, and Gorup-Besancy. It is the object of the author to prepare a work which will not only be useful to specialists in physiology, but to physicians, by whose researches the most important facts in the chemical history of the body have been discovered in the past, as they doubtless will be in the future.

FOUR shocks of earthquake were felt at Mineo, in Sicily, early on the morning of the 5th.

THE severe thunderstorms of October 7, 8, 9, 10, which raged in several parts of France with an almost unprecedented fury, were preceded by strong siroccos in Algeria, where the heat had been quite oppressive. The thunderstorms advanced in France from the south northwards, and even in the British Channel strong south gales were felt. The perturbation lasted during five days, when the magnificent weather which had marked the beginning of October returned.

THE large balloon, the *Crusader*, which escaped from the Royal Arsenal, Woolwich, on Monday afternoon last, descended in the Port Meadow, near Oxford, at 7 o'clock the same evening.

AN interesting account of the annual fungus foray of the Woolhope Club will be found in the *Gardeners' Chronicle* of October 12.

THE *Courrier de Bone* says that a singular phenemenon was observed at Clousel, in the vicinity of Hammam Mex Kontine, one of the most celebrated thermal bathing-places in Algiers. After an earthquake which took place in the beginning of September, an immense rock was precipitated from the mountain. Some inhabitants visiting the place found the opening of a grotto at the bottom of which a lake was discovered. The water is quite fresh and almost at zero Centigrade.

ACTIVE preparations are being made for the meeting of the Social Science Congress at Cheltenham on the 23rd instant.

CAPTAIN PATTERSON, Superintendent of the U.S. Coast Survey, has lately initiated a very important undertaking in connection with the work of the Survey, namely, in determining the extent and position of the oyster beds of the Chesapeake Bay, primarily with reference to the formation of oyster reefs, and their interference with navigation, but broad enough in its scope to serve as the basis of a critical investigation of the whole subject of the oyster fisheries and oyster culture in the United States. It is somewhat curious that the best article upon the statistics and distribution of the oyster in America is from the pen of Capt. Broca, a French officer sent over some years ago by his government to investigate this subject. The work is being prosecuted in the Chesapeake Bay by the Coast Survey steamer *Palinurus*, Mr. H. J. Rice, formerly of Johns Hopkins University, looking more particularly after the natural history features, such as the embryology and development of the oyster, &c. After the survey and investigation have been completed in Chesapeake Bay, the exploration will be extended to other points on the coast. For the better purpose of furnishing the required data for a critical investigation of the subject, the party, in addition to determining the depth of water in which the beds are situated, will secure samples of the water itself, with specimens of the oyster, and the temperature and currents will be observed, the whole work being conducted in accordance with the best principles of modern research.

M. THIERS' long-talked-of work on philosophy will soon be published; it is in the hands of copyists, who will finish their work this week. The work will include scientific subjects. It will be published in three volumes, but the first is the only one which has been completed. The last two volumes have not been revised by the author. M. Thiers began the work in 1864, after having received lessons in astronomy from Leverrier and in chemistry from Sainte Claire Deville. It was interrupted from 1870 to May 24, 1874, when Thiers was obliged to resign the presidentship of the French republic. But it underwent some interruption from January, 1877, when the illustrious author was appointed by the Chamber of Deputies President of the Commission for the Reorganisation of the Army. At St. Germain, when he suddenly died, he was busy re-writing his second volume.

MR. HORMUZD RASSAM, we learn from the *Times*, who returned to England in July last, bringing with him a rich collection of Assyrian antiquities, the result of his last expedition to explore the ruins of Ancient Nineveh, is about to start upon a second and much extended tour of exploration. The expeditions of the late George Smith and other explorers

during the last few years have been greatly impeded by the restricted nature of the firmans granted, and constant disputes were arising as to the area over which the firman extended. Mr. Rassam has succeeded in obtaining a series of sufficiently open permits to enable the new expedition to assume the nature of a roving exploring party. The new firman includes the whole of Mesopotamia, embracing the region around Mosul—that is, the sites of Nineveh, Kalakh, and the ancient city of Assur, the site of which is marked by the mounds of Kileh Shergat. A special firman has been obtained to enable Mr. Rassam to commence explorations in a hitherto untouched field—the districts of North-Eastern Syria. This region, the country which once formed the seat of the powerful Hittite kingdom, having for its capital the city of Carchemish, is as yet a *terra incognita* to explorers, and as its annals when discovered will form an important link in the chain of history which binds Assyria to the West, great results may be expected from Mr. Rassam's explorations in this district.

WE have on our table the following books:—"Pleasant Ways in Science," R. A. Proctor (Chatto and Windus); "Ancient History from the Monuments of Sinai," S. H. Palmer (S.P.C.K.); "Crystallography," H. P. Gurney (S.P.C.K.); "Bluthendiagramma," 1st and 2nd Parts, Dr. A. W. Eichler (Engelmann); "Studies from the Physiological Laboratory of University of Cambridge" (University Press).—London Science Class-Books (Longmans):—"Botany, Morphology, and Physiology," W. R. McNab; "Botany: Classification of Plants," W. R. McNab; "Hydrostatics and Pneumatics," P. Magnus; "Invertebrata and Vertebrata," Prof. Macalister; "Motion of the Moon," Dr. S. Newcomb (Washington); "Physical, Geological, and Geographical Map of Great Britain," Prof. Ramsay (Standford); "Meteorology of the Bombay Presidency," Charles Chambers; "Karl Ernst von Baer," Dr. Stieda; "Karl Friedrich Gauss, Hauptmann (E. J. Brill); "Report on Iron and Steel as Manufactured by Messrs. Jones and Laughlins," R. H. Thurston; "On the Equilibrium of Heterogeneous Substances," Parts 1 and 2, J. W. Gibbs; "Skizzen aus West Afrika," Oskar Lenz (A. Hofmann); "Les Produits de la Nature," A. J. C. Geertz (C. Lèvy); "La Prévision du Temps," W. de Fonvielle.

THE additions to the Zoological Society's Gardens during the past week include a Cross Fox (*Canis fulvus*) from Colorado, presented by Mr. Wilfred G. Marshall; a Common Otter (*Lutra vulgaris*), European, presented by Mr. W. H. Baylis; a Brown Mynah (*Acridotheres fuscus*), a Pied Mynah (*Sternopastor contra*) from India, an Indranee Owl (*Syrnium indranee*) from Ceylon, presented by Capt. J. Murray; four Egyptian Geese (*Chenalopex ægyptiaca*) from the Cape of Good Hope, presented by Mr. Justice Denyssen; two Leopard Tortoises (*Testudo pardalis*) from the Cape of Good Hope, presented by the Rev. G. H. R. Fisk, C.M.Z.S.; a Collared Peccary (*Dicotyles tajaçu*) from South America, deposited; a Red-Sided Eclectus (*Eclectus polychlorus*) from Malacca, a Black-Footed Penguin (*Spheniscus demersus*) from the Cape of Good Hope, four Chinese Turtle-Doves (*Turtur chinensis*) from China, purchased; a Hybrid Mandrill Monkey (between *C. mormon* ♀ and *M. cynomolgus* ♂), an Indian Muntjac (*Cervulus muntjac*), born in the Gardens.

ON THE PRESENCE OF DARK LINES IN THE SOLAR SPECTRUM WHICH CORRESPOND CLOSELY TO THE LINES OF THE SPECTRUM OF OXYGEN[1]

THE measurement of the wave-lengths of the dark lines of the solar spectrum obtained by photographs, and the construction of a chart of the same, has for many years occupied my leisure time. As a result of the investigations connected with this work, I have arrived at the belief that oxygen as well as other non-metallic gaseous elements are represented in the solar spectrum by dark lines in the same manner as metallic substances. The lines in the case of oxygen are, however, very faint when compared with those produced by metals in the vaporous state.

The apparatus employed in these investigations may be briefly described as follows: 1st, a spectroscope for photographing the normal solar spectrum. As my purpose was to obtain photographs in which the positions of the lines should be as true as possible, I resorted entirely to the process by reflection, *and at no time did the solar rays pass through glass*; all error that might arise during refraction was thus avoided. The mirrors of the heliostat were of flat glass silvered, the silver-surface being polished served as the reflector. The surface of the concave-mirror employed to bring the image of the slit to a focus, was also silvered and polished. Gratings of 4,800 and 9,600 lines to the English inch, ruled on glass by a machine constructed by myself and by my assistant Mr. Sickels, and also an admirable one of 17,280 lines to the inch, for which I am indebted to Mr. Rutherfurd, were used. These were silvered with a thin coating, and the unpolished silver surface employed to give spectra by reflection. With the 4,800 line gratings the photographs were in the 1st and 3rd orders; with these of 9,600 lines in the 3rd order, and with 17,280 in the 1st and 2nd orders. The accuracy of the gratings was tested with satisfactory results by taking photographs in equivalent orders of spectra on each side of the normal. The photographs for the determination of the wave-lengths of the solar spectrum were in sections of eighty to one hundred and fifty wave-lengths. The gratings were adjusted to the line of no deviation for the centre of each section of the spectrum, as it was photographed.

The wave-lengths of the lines of the spectrum were carefully measured on the original photographs, by projecting them upon a scale of wave-lengths, each wave-length being five millimetres in extent. The scale was drawn upon slips of paper, which had been glued to strips of well-seasoned pine wood cut with the grain. The lantern used for projection was that described in this journal for April, 1878. The distance of the lantern from the scale, and the consequent magnifying power, was so adjusted as to make the leading lines of the photograph coincide with the same lines of Ångström, drawn in their proper position below the scale as is shown in the diagram given later on. Thus the positions of the lines in each section of one hundred or more wave-lengths were all made visible at once, and the errors in Ångström's chart corrected. From 4045 to O in the ultra-violet the leading lines of Cornu were employed. Among the advantages presented by this method of studying and measuring the lines of the spectrum we may mention the opportunity offered for several persons to inspect at the same time the details of the section under examination, and submit them to intelligent discussion. To this we may add the facilities offered for comparing many photographs with each other by marking below the scale the peculiarities of one, and then projecting the others in order upon the marks made. In this way the effects of duration of exposure and manner of development of the image, together with the variation in the size of the slit and focal distance may be investigated, and their action on the details of the picture determined. Pictures may even be placed face to face, one a little above the other, and examined in that position by projection. From the measures thus obtained a chart of the spectrum was constructed, which extended from E in the green to P in the ultra-violet. The values assigned to the wave-lengths in this chart are those of Ångström, and it is my purpose to present the positions and characters of certain of these lines in this communication.

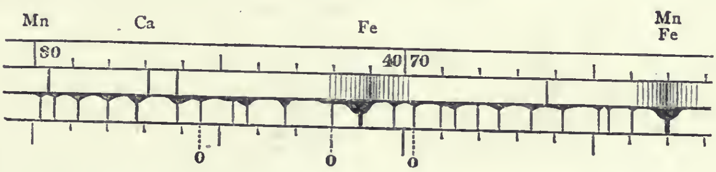
The great increase in the number of lines in the chart made from photographs by Mr. Rutherfurd's grating, compared with that of Ångström, led me to collect all the measurements of spectrum lines of elements that I could find, for the purpose of determining the character of the newly-measured lines. On comparing the lines of the spectra of oxygen, nitrogen, and air, as given in Watt's index of spectra, from the researches of Thalén, Huggins, and Plücker, I was struck with the number of approximate coincidences between the wave-lengths of oxygen lines and those of dark lines in my map. Attempting to make a close comparison of the oxygen with the solar lines I was confronted by the following difficulties, viz.: the measurements

[1] By John Christopher Draper, M.D., LL.D., Professor of Natural History in the College of the City of New York. From the *American Journal* for October.

of Thalén, Huggins, and Plücker were given in wave-lengths only, fractions being omitted altogether. Error amounting to half a wave-length could therefore exist in the position of a line, according as it fell on one side or the other of a figure on the scale expressing a wave-length. In the values given to the air-lines by Ångström in his chart, this difficulty did not exist; I therefore attempted the use of Ångström's values, employing the work of Huggins and Plücker, to separate as far as possible the oxygen from the nitrogen lines. This operation was, however, quickly discarded; because of the great differences existing between these authorities regarding the wave-lengths of a number of oxygen and air-lines. To obviate this trouble, I made photographic measurements of the lines of the electric spectrum of oxygen by the method detailed below.

The apparatus employed consisted of a spectroscope with two flint glass prisms of 60°, adjusted to the minimum deviation of D′. Collimator and telescope objectives, achromatics of ten inches focus. This was used to make photographs of the spectra given by the condensed electric spark in oxygen, in air, and in nitrogen. When so employed the eye-piece of the telescope was removed, and a camera placed in its stead. The slit was sometimes made as narrow as was possible. The induction-coil was one of Ritchie's, giving a ten-inch spark, and having a hammer current-breaker driven by clock-work. The battery was three two-gallon bichromate cells, the elements were large, but just touched the fluid when the battery was in operation. The large mass of fluid in proportion to the immersed area of the elements served to supply a very uniform primary current. The condenser on the secondary current consisted of ten glass plates, each having a tin-foil coating of thirty-six square inches. One or more of these plates could be thrown into the circuit as occasion required. By this arrangement a number of photographs of the electric spark, between platinum and iron points, in atmospheres of oxygen, and of oxygen and nitrogen, were made. The positions of the iron and oxygen lines in these were measured, as in the solar photographs, by projection under a suitable magnifying power. The centre of each line was the portion from which measures were taken in all cases. The wave-lengths of the oxygen-lines were then determined by means of a curve, which from λ3864 to λ4414·75 was based on the iron lines of the same spectrum. In all forty-seven iron lines in this extent of the spectrum, or about one to every eleven wave-lengths were used. The values assigned to the iron lines were those obtained in my chart of the solar spectrum. By this method of measurement errors arising from maladjustment of two spectra were avoided. From λ4414·75 to λ4705 the iron lines did not photograph; I was therefore obliged to construct this portion of the curve from the wave-lengths of oxygen and air-lines already given by various authorities, selecting those values in which they agreed. From 3864 to 4414·75 the results are therefore accurate. From 4414·75 to 4705, though they are approximate, the error, if any exists, must be very small. The measurements to fractions of a wave-length were obtained by constructing the curve on a scale of sufficient magnitude.

In illustration of the great number of lines presented by my chart of the solar spectrum, as compared with that of Ångström, I give a small section extending from 4062 to 4080, within which the oxygen group 4069·80—4072·10—and 4075·50 falls. On the upper part of the diagram the symbols of the elements are placed, to which, according to Ångström, corresponding lines are found in the solar spectrum. On the first space below the line is the scale of wave-lengths, each wave-length being five millimetres in extent. In the second space the lines of Ångström's chart are given. In the third space the lines measured on the photographs, the vertical portion of each symbol giving the position, and the horizontal portion the width, and also the darkness on an arbitrary scale of one to ten. The darkest lines encroach most on the vertical portion of the symbol. The value 10 is expressed in the symbol of the Mn Fe line 4063, and the value 1 in that of the line 4068·05. Other features of the lines are shown by the manner in which the upper part of each of these symbols is drawn. Beneath the spectrum-lines the scale is repeated, and the position of the



oxygen lines indicated. In addition to the lines already mentioned as being in Ångström's chart, lines of the following elements appear in this space, viz., Fe 4063, Pb 4066, Sr 4078, Bi 4080. The correspondence between these values and the wave-lengths of the lines in the photographic spectrum is as close as could be expected, seeing that the authorities do not give fractions of wave-lengths. The Te line is represented in the spectrum by the Mn Fe line 4063, the Pb line by the spectrum line 4065·7, the Sr line by the line 4077·9, and the Bi line by the line 4079·8.

Inspection of the diagram also shows that, while the Mn Fe 4063 lines are coincident in both charts, the Fe line 4071 of Ångström reads 4071·25 in the photographic chart, and the unassigned line 4076·25 of Ångström reads about 4076·20, in my chart, the two lines being nearly coincident. In the photographic chart the relations of the lines to each other as regards position are accurately presented, and where these differences occur the positions given in the photographic chart must be correct. The total number of lines in the two charts is also worthy of notice. In the eighteen wave-lengths represented in the diagram Ångström gives six lines, while the photographic chart gives twenty-four. Of Ångström's lines five are assigned to different metals, if we give the line 4066·25 to Pb, and one is unassigned. In the photographic chart these lines also appear, and in addition the lines of Bi and Sr, together with the three oxygen lines. Out of the twenty-four lines ten are assigned to various elements, leaving fourteen to be accounted for, and many of these are moderately strong lines. The oxygen lines represented in the diagram are among the strongest in the electric spectrum of oxygen, yet the equivalent lines in the solar spectrum are faint when compared with the lines of Ca and Fe. This would seem to indicate a low absorbing power in the gaseous non-metallic elements, as compared with the same power in the case of metals in the vapourous state. The existence of a difference like this would explain why it is that many of the lines in the solar spectrum which represent oxygen have been overlooked. Some of these lines have, however, been observed, Ångström himself giving in his chart a number of lines not assigned by him nor any one else to other elements, which are very nearly coincident with the oxygen lines, as determined by the photographic method, as will be seen in the table at the close of this article.

As it is not possible, in the space to which we are limited, to give diagrams of all the portions of the solar spectrum which contain oxygen lines, we present in the following table the positions in that spectrum of all the oxygen lines that were obtained in the photographs of the electric spark in that gas. The first column contains the wave-lengths of certain lines in the chart made from photographs of the solar spectrum; the second the wave-lengths of the lines of the condensed electric spark in oxygen; the third Plücker's lines of oxygen, which are much more numerous than those of Huggins, which are presented in the fourth column, while the fifth column gives the lines of Ångström's air spectrum, which may be credited to oxygen. The term free in the first column is used to indicate the fact that no element has heretofore been found to give a line within two or three tenths of a wave-length of that position. It is therefore free to be assigned as an oxygen line. The chemical symbols on the other lines show that the element indicated has been assigned to that line, and shares it with oxygen. The number of lines of greater wave-length than 3961·60, which are free from other elements, and which are assignable to oxygen, is good evidence of its presence in the solar envelopes.

DRAPER. Lines of photographic chart of solar spectrum, with their condition.	DRAPER. Lines of electric spark in oxygen.	PLÜCKER. Lines of oxygen.	HUGGINS. Lines of oxygen.	ÅNGSTRÖM. Lines of spark in air attributed to oxygen.

The table presents what may be called the oxygen region of the spectrum, only a few oxygen lines lying outside of its limits. As this also happens to be the region in which our photographic apparatus and chemicals were most sensitive, we are enabled to present measurements of the majority of the lines of oxygen. It will be noticed that though the oxygen lines of greater wave-length than 4704·65 are wanting, on account of their lack of photographic power, this loss is partly made up by the extension of the measurements into the ultra-violet region, where as yet no exact measurements of oxygen lines have been made that I am aware of.

That there should be no error regarding the nature of the chemical element producing the lines, every precaution was taken to have the oxygen as pure as possible. Photographs of the spark in oxygen, between points of the purest platinum that I could procure, were also made. These were compared with the measured photographs of the spark between an iron and a platinum terminal, and provision was thus made for the detection of any error that might have arisen from impurity in the iron used in the terminal. As these photographs of the spark between platinum terminals in pure oxygen presented all the lines given in the table, these lines may be regarded as true oxygen lines. In addition to the oxygen lines given, the following feeble lines were observed, regarding the nature of which I was not quite satisfied, as they did not pass entirely across the spectrum, viz., 4490·30—4505·80—4525·50—4548·75. In the space extending from 4254·30 to 4345·15, many of the oxygen lines are assigned to wave-lengths occupied by other elements; for example, Cr, Ca, Sb, Ti, C, Bi. As other lines of these elements did not present themselves in the measured photographs, and as the lines in question were also found in the photographs of the spark between platinum terminals, they are to be regarded as true oxygen lines, although they are not given by other authorities. In some of the instances in which elements in addition to oxygen are assigned to a weak line in the solar spectrum, it is very possible that such assignments are in error, because of a lack of fractions in the determinations of the wave-lengths of these additional elements. Apparent discrepancies regarding wave-lengths in my determinations, and those of the other authorities, are sometimes explained by the fact that a line which is recorded as single in one case, is given as two lines in the other. It is also worthy of remark that in almost every instance in which a line is presented by one authority and omitted by the others, it is to be found in the column containing the photographic determinations, and is an evidence of the superiority of this method of recording the existence and positions of spectrum lines throughout the region over which it can act.

Examination of the table shows that the differences between the wave-lengths obtained for the lines of the electric spectrum in oxygen and the lines of the solar spectrum are very small. Out of the sixty-five lines of the solar spectrum which are, as we have seen, assignable to oxygen, in seventeen the coincidences are absolute; in four the difference is only five one-hundredths of a wave-length; in twenty-two, ten one-hundredths of a wave-length; in four, fifteen one-hundredths of a wave-length; in eleven, twenty-one one-hundredths of a wave-length, and in the remainder the greatest difference is only thirty-five one-hundredths of a wave-length, or about that which Ångström has made in different measurements of the same line in the solar spectrum.

The small figure attached as a power to each wave-length of the electric and solar spectra in the table is a proximate expression of the photographic strength of that particular line in each spectrum, and an examination of these upholds the statement made in a preceding paragraph that the oxygen lines of the solar spectrum are very weak when no other element furnishes a line which falls on the same wave-length. Of course photographic must not be compared with visual intensities, for as the one diminishes in the less refrangible regions of the prismatic spectrum the other increases. An example of coincidence in the lines of different elements, and consequent increment in strength, occurs in the line 4118, and probably in the line 4303 also, though it is supposed to be free.

In conclusion, I give a list of certain lines in Ångström's chart which have not as yet been assigned to any element, together with the wave-lengths of the same lines in my solar and electric spectra. From this table it will be seen that Ångström himself observed a number of lines, the relations of which to elementary bodies no one has as yet demonstrated, and which I believe represent the oxygen in the solar envelopes.

The subjects presented in this communication may be briefly summed up as follows :—

1. The resort to the process of reflection in producing and photographing solar spectra, and thereby avoiding certain errors, and the employment of the silvered surface itself of a glass grating.

2. The extension of the measurement of oxygen lines into the ultra-violet region.

3. The measurement in the region of less refrangibility than H, of lines of oxygen not heretofore recorded, and the use of projection as a method of measurement.

4. The establishment of a close relationship in position between certain lines in the solar spectrum and the lines of oxygen; the slight differences that exist being assignable to the experimental difficulties in the way of making accurate measures of the oxygen lines, and falling within the limits of error of experiment.

5. The evolution of the fact that the lines of the solar spectrum which appear to correspond to the lines of oxygen are weak, or faint, and show that that gas possesses a feeble absorbent power when compared with metallic vapours or gases like H, Fe, Ca.

6. The demonstration that in Ångström's chart there are many lines not assignable to any elementary body, and that these lines occupy very closely the positions of certain oxygen lines.

7. The suggestion that the proof of the presence in the solar envelopes of oxygen, and other substances giving faint lines, is a problem not to be solved by the comparison of two spectra of small dispersion. The solar spectrum in certain parts is so crowded with lines presenting all kinds of details, that the only satisfactory way is to make measures of the positions of these lines on a large scale, and as truly as possible, and then compare with these the most accurate measures of oxygen lines that can be made.

CYON'S RESEARCHES ON THE EAR[1]

II.

HAVING now described, at what we hope our readers will not consider inordinate length, the history of the subject up to the time when Dr. de Cyon commenced his second series of experiments, a history which he gives in the first part of his thesis in a very clear and impartial manner, we shall now give a short account of the new matter contained in the second part. This may be arranged under two heads—(1) experiments undertaken chiefly with the view of testing the kinetic theory, and (2) the statement of his own theory and arguments in support of it.

The experiments have obviously been made with extraordinary care and skill. Dr. de Cyon succeeded in producing the lesions which he intended to produce, without injuring any other part, and in most cases with scarcely any loss of blood; we can thus observe the effects of any particular operation without the slightest complication from concurrent injury or inflammation of the cerebellum. He has established in the most convincing way, (1) the fact observed by Flourens that the movements of the head always take place "in the plane of the divided canal," or, as we should express it, about an axis at right angles to that plane. (2) That the movements are much more violent, and that the loss of equilibrium is much more persistent, when the corresponding canals of both sides are cut, than when one only, or two dissimilar canals are divided. (3) That when all six canals are destroyed very violent and complex convulsions occur and continue for several days. If the animal survive this stage it gradually attains a condition in which its movements are effected with great deliberation, and in which the sense of sight is absolutely necessary to enable it to direct itself. These experiments were made upon pigeons, upon rabbits, and upon lampreys, the latter animals being especially interesting as possessing only four canals, two on each side.

So far, the results of the new experiments confirm and render more precise the knowledge derived from previous investigations, and they are in perfect accordance with the kinetic theory. One point, however, requires special notice.

Dr. de Cyon points out that the first movement made by an animal on the section of a canal, takes place in a direction "from the divided canal." It is not quite easy to make out the precise meaning of this phrase. It may, and probably does mean, that when the *left* horizontal canal is cut the pigeon moves its beak to the right; but, as the operator is at the back of the bird, it may also mean that the *back* of the head moves to the right and away from the divided canal. Judging, however, from the experiments upon the vertical canals, it is most probable that Dr. de Cyon means that the first movement takes place in such a manner that the ampulla of the divided canal precedes the canal. If this be the case, and if, as seems reasonable, we assume that the first effect of the division is stimulation and not paralysis, and that the movement is a compensatory one—that is, the result of an effort to preserve the same position—we are forced to the conclusion that the canal is affected by a rotation in which the ampulla *follows* the canal, contrary to the view somewhat hesitatingly expressed by Brown and Mach.

Dr. de Cyon has, however, made several experiments, the results of which cannot so easily be harmonised with the kinetic theory. These experiments were made expressly to test the truth of this theory, and in his opinion their results render it untenable. As Mach holds that change of pressure in the ampullæ excites the ampullary nerves and produces a sensation of rotation, Dr. de Cyon devised and executed a series of experiments so arranged that the pressure in the ampullæ should be changed, without injury to the membranous canals. 1. He opened the bony canal and allowed the perilymph to escape. 2. He opened the utricle and allowed the endolymph to escape, and observed that the whole membranous labyrinth collapsed. 3. He introduced into the space containing the perilymph small rods of dried laminaria; these rods slowly swelled by imbibing moisture, and must have considerably increased the pressure in the interior of the cavity. In none of these cases did he observe any trace of the Flourens phenomena. 4. He replaced the perilymph by a lukewarm solution of gelatine, which solidified, and inclosed the membranous labyrinth in an approximately rigid case. Still no Flourens phenomena were observed, but these at once occurred on pricking the membranous canals through the solid gelatine.

Dr. de Cyon further mentions as an argument against Mach's view, the fact that periodic changes of pressure occur in the contents of the labyrinth, synchronous with the heart's beat, and evidently connected with the change of arterial pressure. This, he thinks should, on Mach's hypothesis, produce irritation of the nerves and sensation. It must, however, be observed, that this change of pressure is produced simultaneously in all the six ampullæ, and that therefore the resultant rotation perceived would be zero.

But by far the most important evidence in opposition to the kinetic theory is derived from the section of the whole auditory nerve. Dr. de Cyon succeeded in performing this operation without serious injury to any other part, and found that rabbits, in which both of the auditory nerves had been divided, and in which, therefore, all nervous connection between the semicircular canals and the brain had been cut off, showed, after being subjected to rotation, the same symptoms of vertigo observed by Mach in the case of normal rabbits. It is unfortunate that Dr. de Cyon has not given further details of this most important experiment.

External irritations which, when small, are perceived only by the organs specially fitted for their perception, as a rule act, when very intense, upon other organs. Thus a feeble sound can

[1] Recherches expérimentales sur les Fonctions des Canaux semi-circulaires et sur leur Rôle dans la Formation de la Notion de l'Espace. Par Elie de Cyon, M.D., &c., Lauréat de l'Institut de France. Continued from p. 635.

only be heard, a small quantity of an odoriferous substance can only be smelled, a dilute solution of a sapid substance can only be tasted, but a very loud sound can be felt by producing vibrations sensible to the nerves of the skin; ammonia gas attacks the mucous membrane of the nose, and mustard bites the tongue. These are not sensations of hearing, smell, or taste, but they are sensations produced by external irritations which, when feebler, are perceptible by these special senses only. It is not, then, unreasonable to suppose that sudden and violent changes of rate of rotation should be perceived by the shock communicated to all the soft and movable parts of the body, although slighter changes may be perceptible only by the special organ of the sense of rotation. The experiment just mentioned is undoubtedly a crucial one, but, in order to obtain from it a decisive answer, it would be necessary to make a series of comparative trials, with varied rates of rotation, upon normal rabbits, and upon rabbits whose auditory nerves had been divided; if no difference is observed, even with moderate change of rate, the kinetic theory must be abandoned.

A great deal of valuable information might be obtained by carefully testing the delicacy and accuracy of the sense of rotation in deaf-mutes. Many deaf-mutes have not only the cochlea, but the whole internal ear, destroyed; if, then, the inmates of deaf and dumb establishments were systematically tested by means of such experiments as Mach and Brown made upon themselves, experiments which would, no doubt, greatly interest and amuse them, and if the condition of the internal ear were, in each case of *post-mortem* examination of a deaf-mute, accurately noted, we should soon obtain a mass of information which would do more to clear up the relation between the sense of rotation and the semicircular canals than any number of experiments on animals unable to describe to us their sensations.

We cannot pass from this criticism of the kinetic theory without noticing a passage in Dr. de Cyon's thesis which seems to show that he has not fully appreciated the bearing of this theory:—"Quelques mots seulement pour mieux faire ressortir l'invraisemblance *à priori* de la théorie de MM. Mach, Crum Brown et d'autres. Comment admettre que les canaux semi-circulaires servent à nous informer sur la rotation de la tête, quand nous voyons les mêmes organes parfaitement bien développés chez les animaux qui, comme les grenouilles ou les poissons, ont la tête presque immobile et qui d'ailleurs, pas plus que les autres animaux, n'exécutent pas habituellement des mouvements de rotation?

"Pourquoi justement la présence d'un organe des sens pour un mouvement peu habituel et pas pour beaucoup d'autres, pour les mouvements que les animaux exécutent continuellement?"—P. 47.

No doubt a frog or a fish cannot move its head freely without at the same time moving its body, but head and body together move and perform frequent and rapid rotations. Whenever a fish or other animal changes the direction of its motion, rotation takes place, and a knowledge of the amount and of the axis of this rotation is necessary if the animal is to retain any sense of its orientation. Of all animals a fish, moving and turning with great rapidity and sharpness in a dense medium often affected by complicated currents, seems to have most need of such an organ which serves the same purpose as a ship's compass, an instrument surely not useless because a ship is rigid and does not habitually perform movements of rotation.

We have already alluded to some of the phenomena of optical vertigo. This subject is discussed at considerable length by Dr. de Cyon, and it is therefore right that we should here explain somewhat fully the opinions held in reference to it by various experimentalists.

The phenomena themselves are, in the main, well known. If we rotate about a vertical axis either actively (that is turning ourselves) or passively (that is being turned round on a movable chair or platform by an assistant) we are at first fully aware that we are turning and that external objects are at rest; gradually external objects seem to move round us in a sense opposite to that of our real motion. If at this stage we stop we not only feel that we are being turned round in the opposite sense to that of the previous real motion, but we see, or think we see, external objects turning round. These two imaginary rotations, viz., that of our body which we feel, and that of external objects which we see, take place about the same axis, in the same sense and at the same rate. The axis is parallel to the line in the head which was the axis of the original real rotation, and the sense is, as already explained, contrary to that of the original rotation. These facts are well known and were fully described by Darwin in the "Zoonomia" and by Purkinje. Another phenomenon closely connected with them was first noticed by Purkinje, and has since been investigated by Breuer and by de Cyon. When a real rotation of the body takes place the eyes do not at first perfectly follow the movement of the head. While the head moves uniformly the eyes move by jerks. Thus, in the diagram, Fig. 3, where the abscissæ indicate time and the ordinates the angle described, the straight line $a\ b$ represents the continuous rotatory motion of the head and the dotted line the discontinuous motion of the eye.

Here it will be seen that the eye looks in a fixed direction for a short time, represented by one of the horizontal portions of the dotted line $a\ b$, and then very quickly follows the motion of the head, remains fixed for another short time, and so on. After the rotation has continued for some time the motion of the eye gradually changes to that represented by the dotted line $c\ d$ in Fig. 4. The eye now never remains fixed, but moves for a short time more slowly than the head, then quickly makes up to it, then falls behind, and so on. At last the discontinuity of the motion of the eye disappears, and the eye and head move together.

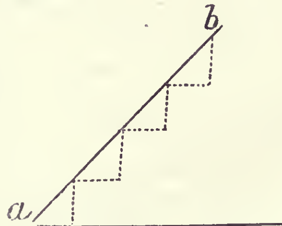

Fig. 3.

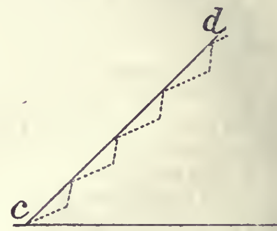

Fig. 4.

If now the rotation of the head be stopped (of course the body stops also) the discontinuous movements of the eyeballs recommence. They may now be represented by the dotted line in Fig. 5.

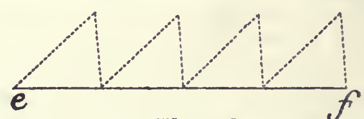

Fig. 5

Fig. 6.

The intermittent motion of the eyes gradually becomes less, passing through a condition such as that shown by the dotted line in Fig. 6, and at last ceases. The consideration of these oscillatory motions is greatly simplified if we draw diagrams similar to the above, but in which $\frac{dy}{dx}$ is made proportional to the *apparent* rate of rotation, that is, to the rate of rotation as perceived by the observer, instead of to the real rate as measured or inferred from external observations.

The *apparent* motion of the head and of the eyeballs is shown in Fig. 7 when uniform real rotation is kept up until it ceases to be perceived, and is then suddenly stopped.[1] The accented letters a', b', &c., correspond to a, b, &c., in Figs. 3, 4, 5, and 6.

We now see what is the real nature of the oscillatory movements. The eye remains for a short time in an apparently fixed

[1] In order to represent accurately the phenomena, the oscillations should be much more numerous and of course smaller. As five or six complete turns are required before all sense of rotation is abolished, and as Dr. Breuer finds at least ten oscillations in one complete turn, there should be at least fifty between a' and e'. These could not be represented without making the figure either very large or very indistinct. Such diagrams are not used by any of the physiologists who have investigated the subject, and must not be interpreted too rigidly, as both the duration and the extent of the oscillations vary considerably. The figures, however, represent the general nature of the phenomena sufficiently for our purpose.

direction, that is, in a direction which the experimenter, judging from his sensation of rotation, concludes to be fixed, then rapidly returns to its original position relatively to the head, again for a short time looks in an apparently fixed direction, and so on.

Some physiologists have considered these oscillatory movements as the cause; others—and notably Dr. de Cyon—regard them as the effect, of the visual vertigo. The latter opinion seems the more reasonable; and indeed both visual and tactile vertigo seem to be matters of judgment rather than of sensation. When the real rotation stops the experimenter perceives, by his sense of rotation, that his head is turning round; he *feels* that his body and the chair on which he sits are at rest relatively to his head; he *sees* that external objects are at rest relatively to his head; and he concludes that, as his head is turning round, his body, his chair, and all external objects must be turning round also—his eyes oscillate precisely as they would do if all these imaginary rotations were real.

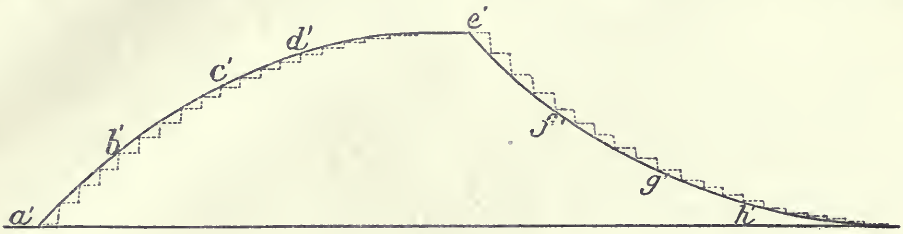

Fig. 7.

Similar oscillatory movements of the eyeballs are described by Dr. de Cyon as resulting from the section or mechanical irritation of the semicircular canals in rabbits, and are by him referred to reflex action dependent on intimate anatomical connection between the roots of the nerves of the ampullæ and those of the motor nerves of the eye. The points of chief importance noticed by him are:—

1. At the moment of irritation the spasm of the muscles of the eyeballs has a tetanic character; immediately afterwards the oscillations commence, and last for a variable time, depending on the intensity of the irritation, and rarely exceeding half-an-hour. The frequency of the oscillations varies from 20 to 150 per minute.

2. The direction of the oscillations depends on the particular canal cut or irritated. Dr. de Cyon describes, somewhat minutely, the direction in each case, but states that he finds it difficult, on account of the peculiar position of the eyes in the rabbit, to give a precise determination of these directions. From his descriptions we can, however, gather, with considerable probability, that the eyeballs oscillate about an axis perpendicular to the plane of the divided or irritated canal.

3. The oscillations, caused by the irritation or section of any one canal, cease when the opposite auditory nerve is divided; new irritations of the canal then produce only tetanic contractions.

The direction of the initial tetanic spasm is given by Dr. de Cyon, and appears to coincide with what we should expect if rotation with the ampulla *preceding* be supposed to excite the ampullary nerves; this result leads to the suspicion that we may have misinterpreted the author's account of the initial movement of the head on section of one canal in the pigeon.

We have now only to state and examine Dr. de Cyon's theory of the function of the canals and of the part which they take in the formation of the idea of space.

This theory is stated in a very general form, and it is difficult by a single quotation to do full justice to it. We quote, however, two passages in which it is distinctly enunciated, and refer the reader for its full discussion to the thesis itself:—

"Les canaux semi-circulaires sont les organes périphériques du sens de l'espace; c'est-à-dire que les sensations provoquées par l'excitation des terminaisons nerveuses dans les ampoules de ces canaux servent à former nos notions sur les trois dimensions de l'espace. Les sensations de chaque canal correspondent à une de ces dimensions.

"A l'aide de ces sensations, il peut se former dans notre cerveau la représentation d'un espace idéal sur lequel seront rapportées toutes les perceptions de nos autres sens qui concernent la disposition des objets qui nous entourent et la position de notre corps parmi ces objets."—P. 64.

"La disposition des nerfs, dans trois plans perpendiculairs l'un à l'autre, se prête à merveille pour une pareille fonction. Nous pouvons très bien nous figurer comment les sensations d'etendue, dans trois plans, dont la disposition, chez tous les vertébrés, répond exactement aux trois co-ordonnées de l'espace, peuvent être utilisées par notre intelligence pour la construction d'une notion de l'espace.

"Je dirais plus: aucun autre sens ne présente une relation aussi facile à saisir entre la représentation et la sensation, que le sens d'espace, d'après ma manière de voir."—P. 73.

This is not inconsistent with the kinetic theory as explained above. The difference is that that theory does, and Dr. de Cyon's does not, explain what the sensations of the canals are and how they contribute to our ideas of direction or orientation in reference to three rectangular axes.

There are two ways in which we may investigate the action of an organ of sense:—We may examine and compare the information we obtain by means of the sense under a great variety of conditions; this is the way in which our knowledge of physiological optics has been chiefly obtained: or we may study the effects of injuries of the organ, either occurring naturally or intentionally produced. A detailed theory has, in the case before us, been sooner attained by the first of these ways than by the second. This theory must be tested by experiments carried out in every appropriate way, and, if necessary, must be modified in accordance with their results. We may thus expect to obtain a knowledge of the mechanism of the sense of orientation as complete as that which we have of the mechanism of the sense of sight. Dr. de Cyon's thesis contains the record of a very considerable step in this direction.

ALEX. CRUM BROWN

UNIVERSITY AND EDUCATIONAL INTELLIGENCE

THE President and Fellows of St. John's College, Oxford have just passed the following resolution *nem. com.*: "That independently of the granting of Fellowships for the assistance of research, the college shall from time to time make money grants for that purpose." The granting of Fellowships alludes to a clause in the new Statutes which has just been drafted, in which a Fellowship is set apart for this purpose.

PROF. HUXLEY will lecture at a general meeting of the Working Men's College, Upper Kennington Lane, to be held on the 24th, at 8.30 P.M., to inaugurate the new premises of the College, near Vauxhall Station, one part of which has been fitted up as a chemical laboratory, with all the appliances needed for the study of practical chemistry.

THE New South Wales correspondent of the *Colonies* states that, in consideration of the necessity which is now felt for extending the curriculum of Sydney University and augmenting its teaching powers, the Colonial Government have consented to ask Parliament for an additional annual grant of 5,000*l*. This will enable the Senate to make the following additions to the present course of study:—(1) Mental philosophy, law, history, and English literature; (2) all the education necessary for the medical profession; (3) a complete course of natural philosophy, coupled with mechanics and engineering; (4) the addition of organic chemistry and metallurgy to the chemical school; and (5) biology, including animal and vegetable physiology. The Senate will also be in a position to establish a faculty of science, and to confer the degrees of Bachelor and Doctor of Science, and also degrees in medicine, on those who have received their education in Sydney.

SCIENTIFIC SERIALS

Verhandlungen der k.k. zoologisch-botanischen Gesellschaft in Wien (vol. i. 1878).—This volume is in every respect equal to its predecessors, both for variety as well as scientific interest of its contents. The papers which deserve special praise are: Lichenological excursions in the Tyrol, by F. Arnold.—On the metamorphosis of several species of *Tipulidæ*, by Th. Beling.—Remarks on the metamorphosis of insects in the spirit of the theory of descent, by Dr. Fr. Brauer.—Researches on *Phytoptocecidiæ*, by Dr. Franz Löw.—Notes on some new *Cecidomyidæ*, by the same.—On some new exotic *Hesperidæ*, by H. B. Möschler.—Ennumeratio Ichneumonidum, exhibens species in alpibus Tiroliæ captas, by Aug. E. Holmgren.—Other papers of interest are: On the mollusc-fauna of Galicia, by J. Król.—Ornithological notes, by P. Hanf.—On the birds of Ecuador, by A. von Pelzeln.—On ear-shaped grass panicles, by E. Hackel.—On the fungi of Carniola, by Wilhelm Voss.—Note on a new mollusc, by M. Folin.—On some new *Cucujidæ* in the Royal Museum at Berlin, by Edmund Reitter.—Researches on *Lyctidæ*, by the same.—Analytical classification of the species in the genera *Sphindus* and *Aspidophorus*, by the same.—On the influence of changes in the conditions of vegetation upon the forms of the organs of plants, by Otto Stapf.—On a remarkable form of Lenticels, by the same.—On some species of the *Chalcidiæ* genus *Eurytoma*, obtained by artificial breeding, by Dr. G. Mayr.—On the flora of Fiume, by A. M. Smith.

SOCIETIES AND ACADEMIES

London

Royal Microscopical Society, October 9.—H. J. Slack, president, in the chair.—This was the first meeting of the present session. Numerous presents were announced and acknowledged, and Major Festing and John Borland were elected Fellows of the Society.—The president called attention to a specimen of the perforating proboscis of a moth which had been received from Colombo, and compared its structure with that of a species which had been the subject of discussion at a former meeting.—An interesting paper was read by Prof. Owen upon certain fossils found in the middle Purbeck, to which he had given the name of *Granicones*, and which, after careful comparative examination, he had decided to be the dermal scutes of a lacertian closely resembling the now existent Australian species, *Moloch destructor*. He pointed out that the remains found in these rocks were chiefly those of marsupials, and that in the mesozoic strata both animals, plants, and shells had now their only living representatives at the antipodes.—Communications were read from Col. Woodward on the modification of the illuminator for balsam-mounted objects, also from the American Microscopical Congress recommending the adoption of the $\frac{1}{100}$ millimetre as the standard for microscopical measurements.—A discussion ensued, in the course of which it was suggested that much advantage would arise to microscopists from the more careful adherence on the part of makers to the Society's standard screw, and also greater uniformity as to size of tube, eye-pieces, and other mechanical details.

Paris

Academy of Sciences, October 7.—M. Fizeau in the chair.—The following papers were read:—On the irreducible covariants of the quantic of the seventh order, by Prof Sylvester.—Observations on M. Gruey's recent communication on a gyroscopic apparatus, by M. Hirn. He considers the new apparatus presents a special case of phenomena analysed in his own memoir on the gyroscope.—On a singular case of heating of a bar of iron, by M. Hirn. A workman holding a cylindrical iron bar (about 1 m. long and 0·08 in diameter) on another piece so as to be struck with a hammer on the free end, said he felt the bar at each stroke greatly heated and then as quickly cooled. M. Hirn verified this with surprise. He estimated at 35° the sudden variation of temperature. For best observation one should come very near the bar and seize the iron about 0·01 m. from the end struck (a position requiring some faith in the address of the workman!). M. Hirn thinks the phenomenon quite subjective, *i.e.*, one of sensation. In certain conditions, sonorous vibrations affecting the sensitive nerves, may cause at the periphery of the body a sensation of heat, just as, *e.g.*, pressure or a blow on the eyes may awaken in these organs the sensation of light. This view he gives with reserve, and desires physicists to test a bar, in such circumstances, with a Melloni thermometer.—Observations on M. Bouillaud's note inserted in last week's *Comptes Rendus*, by M. du Moncel.—Discovery of two small planets at Clinton (New York), by Mr. Peters.—Second letter of Mr. Watson on the discovery of intra-Mercurial planets. M. Mouchez thought that while the American observations have rendered very probable, or almost certain, the existence of intra-Mercurial planets, they have not sensibly improved the knowledge of their orbit.—Two remarks on the general relation between pressure and temperature, determined by M. Levy, by Herr Weber.—On the manner in which is distributed, among its points of application, the weight of a hard body placed on a polished, horizontal, and elastic ground; identity of this mode of distribution for a plane and horizontal supporting base with that of an electric charge in equilibrium in a thin plate of the same form, by M. Boussinesq.—On the resolution, in whole numbers, of the equation (1) $ax^4 + by^4 = cz^2$, by M. Desboves.—On a new gyroscopic pendulum, by M. Gruey.—Revision of the flora of the Malouines (Falkland Isles), by M. Crie. At present there are about 394 species (Hooker enumerated 368). The compositæ count more individuals than all the twenty-seven other families of dicotyledons combined. The gramineæ occupy the second place. As in most arctic flora, the most numerous are the cryptogams. Algæ have nearly 100 representatives. The author adds nine new species of muscineæ to those described by Hooker.—Researches on the urea of organs, by M. Picard. During digestion, urea is formed in the muscles, the brain, and the liver; these have all more of the substance than an equal weight of blood. During fasting, urea seems to be formed only in the brain and the muscles.—Note on M. Perez' work on the buzzing of insects, by M. Jousset de Bellesme. This is the substance of a paper read to the French Association in August, and giving much the same results as those of M. Perez, communicated to the Academy in September.—On *Trichodonopsis paradoxa* (Clap), by M. Schneider.—Structure and botanical affinities of the cordaïtes, by M. Renault. The order of Cordaïteæ is more nearly related to the Cycadeæ than any other family of Gymnosperms, and the Cycadeæ, including Sigillarineæ, must have reached an immense development at the coal epoch.—On the atmosphere of planetary bodies and the terrestrial atmosphere in particular; remarks on Mr. Sterry-Hunt's recent paper, by M. Meunier.

THURSDAY, OCTOBER 24, 1878

THE CONSERVATION OF RIVERS

THE question of the control of rivers has during the last two years occupied more attention than had previously been bestowed upon it for a considerable period. The disastrous floods in South Wales and other parts of the country in the summer of 1875 caused a great outcry at the time, and this had hardly been forgotten when the evil recurred with still greater intensity, and in some cases more damaging effects in the winter of 1876-77. The immense amount of damage caused by floods in these two years, coupled with the fact that, in the opinion of a great many, they occurred at more frequent intervals than in former years, at length drew the attention of Government to the subject. Consequently in 1877 a Select Committee of the House of Lords was appointed to inquire into the operation of existing statutes in regard to the formation of, and proceedings by, Commissioners of Sewers, and Conservancy, Drainage, and River Navigation Boards; to consider by what means they could be more inexpensively constituted and their powers enlarged so as to provide more efficiently for the storage of water and the prevention of floods. At the same time two other committees of the House of Commons were sitting on the same subject, but with reference only to the River Thames, one dealing with the question of the prevention of floods within the metropolitan district and the other within the whole valley of the Thames. A vast amount of information was collected from the numerous witnesses examined by these committees. Considerable difference of opinion was, as might be expected, found to exist in respect of the causes and best means of prevention of the severe floods experienced of late years in our different river basins, but by far the greater majority of the witnesses agreed that the floods were yearly getting worse than formerly, that the river channels were getting into a worse and worse state of neglect, and, what is a most important point in the practical bearing of the question, that the damage caused was so great that the carrying out of extensive remedial measures could in most instances be made to pay. It would appear at first sight a comparatively simple matter, given the drainage area of the river basin, the intensity and duration of the maximum observed rainfall, and the hydraulic inclination of the river, to calculate the sectional area of channel requisite for the maximum discharge; this is doubtless the case, but unfortunately in the early history of the world the formation of rivers was left entirely to the forces of nature without the professional assistance of a competent engineer. If an engineer of suitable experience were called upon to design a river from source to the sea, he could doubtless successfully accomplish the work, but the problem the legislature is now called upon to deal with is of far greater complexity. Not only have the rivers themselves been doing all they could to make things difficult, meandering in graceful curves through plains where they ought to have gone in straight lines, and silting up where greater depth of channel was necessary, but the inhabitants of the country most interested have followed the same course now for some centuries by constituting themselves under Acts of Parliament into innumerable small drainage boards with certain definite powers within their own districts, but unable and unwilling to join together and act for their general good.

The Select Committee on the Prevention of Floods within the Metropolitan District had a comparatively simple question to deal with. Accurate and long-continued observations on the levels of high water were produced, showing the result of the various works of improvement that have been carried out since it was decided to remove old London Bridge. The tides in the Thames are the resultant of two tidal waves, one reaching the mouth of the river by the North Sea, the other by the English Channel, the former arriving at the river usually about three hours before the latter. But certain conditions of the wind on some occasions bring these two tidal waves together; thus a south-westerly gale accelerates the English Channel wave and retards the North Sea wave, while again the latter may be increased by a north-west wind off the coast of Scotland blowing at the same time. The highest tide on record in the Thames was that of November 15, 1875, which rose to the height of 4 feet 7 inches above Trinity high-water, or 3 feet 2 inches above the predicted height; that of January 2, 1877, exceeded the predicted height by 3 feet 4 inches, and reached a height of 4 feet above Trinity high-water. The conditions producing these results were nearly the same: in the south a south-westerly gale, in the north a north-westerly with an easterly wind blowing up the Thames, combined with a low barometric pressure over the river valley and continued heavy rains. Almost the worst possible concurrence of circumstances having on previous occasions occurred, it will not be too much to predict their recurrence at some future time, and possibly with much more disastrous effects; for whereas the highest tide on record, that on November 15, 1875, was only 3 feet 2 inches above its calculated height, that of December 12, 1845, rose to 5 feet 7 inches above its predicted height, showing that a suitable concurrence of conditions might produce a tidal wave upwards of 2 feet at least above the highest on record. In the face of these facts and the repeated inundations of low-lying parts of the metropolis, it is simply astounding that so little should be done not only to obviate the recurrence of a well-known evil, but to prevent a much worse one from happening. Bearing in mind the great and costly works carried out by the Metropolitan Board of Works in the main drainage of London, the Thames embankments and the numerous new streets, and, finally, also in their last great work of buying up and freeing the bridges, it would appear a small thing to raise the height of the river banks at the few places necessary to prevent the periodical inundations; but though there is no difference of opinion as to the character and extent of the works required, the Select Committee and the Board do not seem to have agreed on the question of how the improvements are to be paid for, and the matter appears again to have gone to sleep.

The general question of the control of the entire river channels is one of much greater complexity than the prevention of the periodic overflows of the Thames

in the Metropolitan District. It was, therefore, with great pleasure that we saw that the President of the Mechanical Section of the British Association, Mr. Edward Easton, did so much to further the consideration of the question by making it the subject of his opening address at the recent Dublin meeting, and the number of papers by various well-known authorities that followed on the different branches of the same subject, with the discussions thereon, still more enhanced its value. The scope of the whole question involves, as well as the prevention of floods, the following considerations, as pointed out by the President:—the supply of pure and wholesome water for domestic and sanitary wants, the supply of water of proper quality and sufficient quantity for industrial purposes, the proper development of water power, land drainage, and irrigation, navigation, and the preservation of fish. It has long been found in most districts that many of these interests are mutually antagonistic, that the use of water for manufacturing purposes and sanitary arrangements interferes with the supply of pure water for domestic purposes in the places lower down the stream; that the utilisation of water-power by the erection of mill-dams and weirs impedes the passage of floods and renders efficient land drainage more difficult, while on most navigable rivers the navigation and drainage interests seem to be constantly in opposition. Before two of the Select Committees referred to much useful information was given by the different witnesses examined, but the absence of discussion left much useful work to be done at the Mechanical Section at Dublin.

The facts most prominently brought forward and the remedies advocated may now be considered. The passage to the sea of the water falling as rain may not only be too much retarded, causing loss to the producing power of the country by submerging large tracts of valuable land for a long period; but it may easily be too much accelerated, causing great loss and inconvenience from drought in summer. Notwithstanding the persistence of rainy weather, so much complained of in our climate, most of our rivers would sink to most insignificant dimensions were not some provision made for impounding the water in times of drought. In the fen country admirable provision for floods was made by the early Dutch engineers employed, who, finding the natural river channels, though adapted for the ordinary flow, quite incapable of containing the flood waters, raised banks a considerable distance back from the natural bed of the river. Long tracts of country were thus inclosed and formed into a channel for the passage of flood waters; and, had the works been completed to the outfalls of the river, or had those outfalls been artificially deepened and straightened in those days to the extent they have since, there is little doubt that the result would have been completely satisfactory. As it is, with the extension of works at the outfall of the rivers, rendered necessary by increasing quantity and size of shipping, the original works have been allowed to fall into decay, or have been so altered by the erection of dams and sluices as no longer to fulfil their original uses. What is required in these rivers, then, is to a great extent merely to restore them to the state they were in when left by their original improvers, continuing the improvement of the outfalls, and removing the shoals and other obstructions that have grown up since that time. To remove the whole of the weirs and sluices would be to take away almost the entire water supply, in time of drought, for agricultural purposes. The weirs will therefore have to be made movable, rendering it an easy matter to retain the water supply in summer, while, by lifting the sluices in good time, on the approach of floods, the channel will be freed of all obstructions. In the case of all the rivers considered—the Thames, the Severn, the Shannon, the Great Ouse, Nene, Witham, and others—it was shown that the channels had been suffering continued deterioration from the formation of shoals and the growth of weeds, and that the dams and weirs erected for the maintenance of the water-level in dry weather were not provided with sufficient sectional area for the flood discharge. The engineering difficulties in the way of a complete improvement of our principal rivers are not at all insurmountable, but the legislation necessary has proved abortive. Each river basin is cut up into a number of drainage districts, formed under Acts of Parliament obtained at various times, and wholly without reference to each other. One district is unable to obtain powers to make improvements in its portion of the river without encountering a determined opposition from the districts below, who find that their works would be imperilled by the alterations; and thus a great proportion of the cost of any improvements is spent in parliamentary contests. There is now an almost general agreement in the opinion that the difficulties in the management of rivers are due to divided authority, and that the question could be satisfactorily dealt with if entire river-basins were placed under the control of one body of conservators. The conclusion arrived at is that each river-basin must be placed under the care of a single Conservancy Board, who shall have to decide on and execute any general scheme for the improvement of the river; that this Board shall consist of members chosen from the various districts Boards, which would have the power of executing minor works in their own districts, not affecting the general *régime* of the river, but subject at all times to the control of the combined Board; that the powers of rating conferred on the combined Board shall extend over the whole river basins, but that a special additional rate shall be levied on those districts most directly benefited by the improvements.

It has been proposed, also, that a Central Board should be established in the metropolis, presided over by a Cabinet Minister, to which appeal from the decisions of the various Conservancy Boards can be made, and that this Central Board shall have powers analogous to the Local Government Board, of issuing provisional orders, to be subsequently confirmed by Act of Parliament, thus greatly diminishing the cost to the local ratepayers of the improvements they desire. At the conclusion of the Dublin meeting a recommendation was made by the Mechanical Section that a Committee of the British Association should be appointed to ascertain what steps should be urged on Government to bring about the undivided control of river basins in this country. As it appears very uncertain what action Government may take on the Reports of the Select Committees of

both Houses on this question, the Council of the British Association may be able to do a work of great national importance by pointing out clearly and definitely what must be done, and by the publication of an annual report on the progress made preventing the subject again being allowed to drop.

STELLAR OBJECTS SEEN DURING THE ECLIPSE OF 1869

It will be remembered by the reader who has interested himself in the published reports of observations of recent total eclipses of the sun, that during the totality on August 7, 1869, at a point in Iowa, called St. Paul's Junction, several observers attached to a party organised by Mr. W. S. Gilman, of New York, remarked below the sun what they termed "a little brilliant," and that one of the number using a small telescope, reported having seen just before the sun disappeared and as he came out again a minute crescent, in a similar direction from the moon. Commodore Sands, then Superintendent of the Naval Observatory, Washington, expressed his regret that these objects should not have been seen by Mr. Gilman himself, who had experience of the use of the telescope and was using a larger instrument than the others who had optical aid—but his "plan of operations" did not permit of it. The facts are thus stated:—A few moments after the corona formed, a small but exceedingly bright point, like a star, was noted independently by four of the party, two of whom it is mentioned were observing without telescopes; it appeared near the limits of the corona, below the moon's disc, and with one exception the observers located it a little to the right of an "anvil-shaped" prominence, or "at about 230° from the north point, reckoning by the east," and it is added that each of the observers felt quite positive that what he saw was truly a star. With respect to the small crescent Mr. Gilman reports that about half a minute preceding totality another member of the party, Mr. Vincent, came to him exclaiming that he saw a miniature-crescent-shaped star under the moon, and asking him to verify the observation, but, interested in his own work, he did not at the moment do so; on Mr. Vincent returning more urgent than ever, Mr. Gilman says he did look in a hurried manner but saw nothing in the few seconds he gave to the search; he afterwards states, however, that he does not think he looked so far away from the moon as the crescent was located in a drawing made immediately after the eclipse by Mr. Vincent; in this drawing it was placed "at one and a half times the moon's diameter from its limb, and to the left of a perpendicular down to the horizon." Mr. Gilman adds he could not connect this crescent with the small star of the other observers, indeed Mr. Vincent estimated the object seen by him at three times as far removed from the moon's limb as the small star, which would assign for the latter a distance of about half a degree, corresponding very well to the expression used by the four observers who noted it, that it was near the limits of the corona. Dr. B. A. Gould, now Director of the Observatory at Cordoba, who observed this eclipse at a different station, gave some attention to a search for any object near the sun which might be an intra-Mercurial planet, and he states he saw the star π Cancri, but did not meet with any other stellar body. This star being at the time in a similar direction from the moon's centre, to "the little brilliant" of the Iowa observers, there has been a pretty general opinion that it was the object remarked by them, and, in conversation with Dr. Gould several years since, I found him tolerably well satisfied that he had thus sufficiently explained their observations. But the discovery, or rather discoveries, of Prof. Watson, lend a new interest to them, and a more strict examination of the circumstances may not be out of place here. The position of St. Paul's Junction is stated to be in latitude 42° 47′ 30″ N., and longitude 19° 5′ 45″ W. of Washington. The totality was observed to commence at 5h. 48m. 4·6s., ending at 5h. 51m. 34s. M.T. at Washington, so that the middle occurred at 10h. 58m. 22s. M.T. at Greenwich, which agrees exactly with a calculation made with the *Nautical Almanac* elements. We will assume 10h. 59m. G.M.T. as the time to which the observations of the brilliant point apply. Correcting the moon's place for the effect of parallax, we find her apparent position at this time to be in right ascension, 9h. 11m. 26·7s., and north declination 16° 13′ 58″; her augmented semi-diameter was 16′ 37″. We must assume that both star-like object and crescent were on an angle of 230°, the latter one-and-a-half times the moon's diameter from her limb, and the former at one-third of this distance, whence, referring to the moon's centre, we have, for the crescent, $\Delta\alpha = -$ 3m. 32s., $\Delta\delta = -42'\cdot7$, and for the bright little star, $\Delta\alpha = -$ 1m. 46s., $\Delta\delta = -21'\cdot4$; and thus,

	R.A. h. m. s.	Decl. ° ′
Stellar object	9 9 41	+ 15 52·6
Crescent	9 7 55	+ 15 31·2

The former was therefore 28′ and the latter 56′ south of the ecliptic.

Now with regard to the star, the presence of which has been supposed to explain the observation of the four observers who noted "the little brilliant," there has been some slight confusion. In a note inserted in the last "Annual Report" of the Royal Astronomical Society it is stated that the object seen "has been satisfactorily identified as the star π^1 Cancri," which is assuredly a mistake. π^1, according to Argelander, is only a seventh magnitude, which is hardly to be glimpsed with the most acute sight in the darkest winter sky. For π^1 no doubt we must read π^2, or 82 Cancri. But this star, also, is of a degree of brightness wholly insufficient to allow of it being possible to discern it at all so near the sun's place without some optical aid in the still illuminated sky-ground, much less to be caught up as a brilliant point of light, with the naked eye; the "Durchmusterung" estimate is 5·8m., which is confirmed by the careful estimations of the second Radcliffe Catalogue, where we find it rated 5·9m., or, in round magnitudes, a sixth. It should be mentioned that the apparent place of 82 Cancri was in right ascension 9h. 7m. 59·5s., declination 15° 28′ 56″, agreeing nearly with that we have found for the minute crescent, but 33′ from the small star. It appears probable, in view of Prof. Watson's discovery, that Dr. Gould may have mistaken an intra-Mercurial planet for π^2 Cancri, and if the statements of the four observers at St. Paul's Junction (one of them, by the way, a lady) are accepted, it can hardly be doubted that they also were

attracted by an unknown object, since in that part of the sky there is no star which could be visible as they describe it. It is significant that Regulus, upwards of 12° from the sun's place, was only noticed as "a glimpse-star" at St. Paul's Junction. J. R. HIND

LAKE DWELLINGS

The Lake Dwellings of Switzerland and other Parts of Europe. By Dr. Ferdinand Keller. Second edition, greatly enlarged. Translated and Arranged by John Edward Lee, F.S.A., F.G.S. Two vols. (London: Longmans. 1878.)

IT is ten years since the first edition of Dr. Keller's valuable work was published, and since that time vast additions have been made to a knowledge of the subject of which it treats. Mr. Lee, besides incorporating in the present edition the whole of Dr. Keller's Seventh Report, gives short accounts of every lake settlement that has been investigated; and an idea of the progress that has been made in this department may be learned from the fact that in the first edition the number of objects drawn and described numbered about 1,500, whereas in the present edition they number between two and three thousand.

The second volume, a thick one, is entirely occupied with illustrations of the portions of lake dwellings that have been found, of the situations in which the remains exist, and of the multitude of objects that have been collected *in situ*. As a frontispiece to the first volume is given an illustration of a restored lake dwelling, which nestling near the shore of a Swiss lake, in a picturesque situation, backed by trees and overtopped by lofty mountains, makes a very pleasant picture. Over the fence which surrounds the edge of the platform we see the sloping roofs of the huts built thereon, and out in the lake two boats fishing by means of nets. There is some difficulty, it seems, as to the question of windows, Mr. Lee contending that the huts must have contained these, as the inhabitants would often have to work at their flint implements by the side of the fire. But we scarcely think windows necessary on this account; we have frequently seen the peasants in Scotland, in the long winter evenings, carry on knitting and other even more delicate work by the light of the fire or at most with the addition of a lighted spill of resinous pine. On the whole, however, Mr. Lee's restoration is likely to be a pretty close approximation to reality, to judge from the mass of data collected in Dr. Keller's work.

After an introduction describing the various forms of lake dwellings, the methods used in collecting the relics, on the original discovery of the dwellings, and a few sensible remarks on the ages of stone, bronze, and iron, each of the lakes in which dwellings have been found is treated of separately, the nature of the remains described, and an attempt made to realise the actual nature of the original work. Sections, for there are no chapters, are devoted to the discussion of special objects found and of special points and circumstances connected with the structures, the life and habits of the builders, and the environment generally. One of the most interesting sections is that on the Geographical Distribution of Lake Dwellings, from which we see that they have been found in many other places besides Switzerland—in Germany, Austria, France, Ireland, Scotland, and Wales. Mr. Lee rightly includes under the general head of Lake Dwellings the Crannoges of Ireland, Scotland, and Wales; for although those of Ireland at least were in several important respects different from the structures found on the Continent, still they have several strong points of resemblance. The reason for the choice of site was no doubt pretty much the same—security from sudden attack. Remains of lake-dwellings have even been found in the heart of London, in the peaty marsh where Finsbury now stands, and where, "in Romano-British times, some outcast natives lived." Gen. Lane Fox describes these remains in the *Anthropological Review* for April, 1867. Dr. Keller has always been adverse to the idea of lake-dwellings having been circular; but just when the English work was completed, Mr. Lee tells us that the author sent him word of remains of an undoubted circular dwelling having been found at Fang, in the Lake of Morat. Very interesting are the sections by Prof. Oswald Heer on the plants of the lake-dwellings, and by Prof. Rütimeyer on the animals.

From the mass of data which has been collected, Dr. Keller gives a very clear account of the general form of these lake settlements, and of the different varieties under which they may be classed. As to the substructure, first of all of pile dwellings, which are by far the most numerous in the lakes of Switzerland and Upper Italy. Piles of various kinds of wood sometimes split, but in general mere stems with the bark on, sharpened sometimes by fire, sometimes by stone hatchets or celts, and in later times by tools of bronze and probably of iron, were driven into the shallows of the lakes, provided they were not rocky, at various distances from the shores. Sometimes the piles were close together, sometimes wide apart. On the level tops of the piles were laid the beams, which were sometimes fastened by wooden pins and sometimes let into mortises cut in the heads of the piles. Sometimes the vertical piles were strengthened by cross timbers below the platform beams. Generally the platform itself consisted of one or two parallel layers, and was of very rude structure, though sometimes the stems were split and joined together with some approach to accuracy. The distance from shore seems to have varied considerably; but it is curious that when a lake dwelling had been inhabited both in the stone and bronze ages, that part evidently used in the bronze age is frequently further from the shore and deeper in the lake than that which belongs to the age of stone. Otherwise, nearly the same mode of construction prevailed in the pile-dwellings during the ages of stone, bronze, and iron. In some cases, at least, there is evidence that the dwellings were connected with the shore by a narrow platform or bridge, formed also of piles. In certain cases, also, it is seen that artificial elevations were made on the bed of the lake by piles of stones brought in boats; one of these boats, still loaded with stones, is to be seen at Peters Island, on the Lake of Bienne. The stones must have been put down after the piles had been driven more or less deeply into the mud.

Certain forms, known as frame-pile dwellings, have been found in the Lake of Zürich. In this form the piles, instead of having been driven into the mud of the

lake, had been fixed by a mortise and tenon arrangement into split trunks, lying horizontally on the bottom of the lake, evidently when the mud was more than usually soft.

Another form of these ancient habitations has been designated fascine dwellings. Instead of a platform supported on a series of piles, Dr. Keller tells us these erections consisted of layers of sticks, or small stems of trees built up from the bottom of the lake, till the structure reached above the water-mark, and on this series of layers the main platform for the huts were placed. In these dwellings upright posts were used as stays or guides for the great mass of sticks reaching down to the bottom of the lake. Fascine dwellings occur chiefly in the smaller lakes, and belong to the stone age.

Another form of lake-dwelling which has been long known, are the Crannoges or "wooden islands," found in Ireland and Scotland; one has also been found in North Wales. "The crannoges, at least in Ireland, were frequently but not exclusively placed on natural islands, or on shallows which approached to this character; sometimes they were built up from the bottom of the lake on the soft mud, exactly in the manner of the fascine dwellings of Switzerland. They are surrounded by a stockade of piles driven into the bed of the lake, so as to inclose either a circle or an oval; the diameter varies from 60 to 130 feet. These piles are usually in a single row, but sometimes the rows are double and even treble. Occasionally the piles are boards, not round stems. The lowest bed within this inclosure is commonly a mass of ferns, branches, and other vegetable matter, generally covered over with a layer of round logs, cut into lengths of from four to six feet, over which is usually found a quantity of clay, gravel, and stones." Although it is probable that both these crannoges and the Swiss lake-dwellings, which it will be seen had much in common with regard to structure, were erected in lakes greatly for the sake of security, still the lake-dwellings were evidently places of permanent habitation, while the Scotch crannoges, at least, are believed by good authorities to have been chieftains' forts and fastnesses for occasional retreat. The crannoges were actually used far into the age of iron, while the Swiss lake-dwellings belong almost exclusively to the age of stone, and disappeared, Dr. Keller tells us, as far as we at present know, about the first century.

With regard to the superstructure of these pile-dwellings, it appears that on the platform was laid and beaten down firmly a bed of mud, loam, and gravel. The framework of the huts consisted of small piles or stakes, and sometimes of the upper or projecting parts of piles, longer than those on which the platform was built. Round the bottom, at least, of the hut a board or skirting was fitted, and the walls or sides were in a great measure made of a wattle or hurdle-work of small branches, woven in between the upright piles, and covered with a considerable thickness of loam or clay. The huts seem in nearly all cases to have been rectangular, though in at least one instance, referred to above, the circular form has been found. As to whether there were internal divisions in the huts no evidence has yet been found, though it seems certain they were thatched with straw or reeds. "Every hut had its hearth, consisting of three or four large slabs of stone; and it is probable from the almost universal prevalence of clay weights for weaving, that most, if not all, of them were furnished with a loom."

Such was, as far as can be gathered from the mine of information contained in Dr. Keller's volumes, the nature of these curious structures belonging to a remote age and a primitive people. But that the builders of these dwellings were considerably advanced beyond the lowest stage of civilisation is evident, not only from the structures themselves, but from the many articles found in connection with them, and which are so copiously figured in Dr. Keller's second volume. Implements, weapons, and ornaments, mostly in stone, but not infrequently in bronze and even in iron, have been found, of elaborate and finished structure. Beautifully wrought and ornamented textures, showing considerable skill not only in weaving, but in embroidery. Fishing-nets, fish-hooks, and boats, these lake-dwellers had, domestic animals and agricultural implements, all showing that, whoever they were, they were well on the way to a fairly high civilisation; they were fishers, hunters, shepherds and agriculturists, and to no small extent manufacturers. "The endeavours of the settlers to live together in permanent abodes and in a sociable manner, is a positive proof that they had long known the advantages of a settled mode of life, such as applies to the lake-dwellings, and that we have to look upon them not as wandering pastoral tribes, still less as a mere hunting and fishing people. A settled union of a great number of men in the same place, and of hundreds of families in the neighbouring bays, would never have taken place if there had not been a regular supply of provisions at all times of the year, and some beginning of social order."

To all interested in the progress of our race, the two fine volumes of Dr. Keller and Mr. Lee are well worthy careful study; they enable the student to put together with wonderful fulness a picture of a form of society that must have had an early beginning, and the dwellings, and implements, and manners and customs of which are full of interest. Considerable light is thrown on the subject of Dr. Keller's work by what we know of existing pile-dwellings in various parts of the world, not the least interesting of which are those found in Lake Mohyra, in Central Africa, by Commander Cameron.

OUR BOOK SHELF

Annual Record of Science and Industry for 1877. Edited by Spencer F. Baird. (New York: Harper Brothers. London: Trübner. 1878.)

THE high opinion which we have previously expressed concerning this excellent annual is sustained by the present volume, which, however, is smaller than its predecessors, owing to a change that has been made in its character. Hitherto the "Annual Record" has consisted of two distinct parts, a summary of scientific progress made during the year, and a series of abstracts of the more important papers and articles in the scientific journals. This dual character it has been found impossible to sustain, owing to the rapid increase in the number of scientific papers, and also probably to the larger range taken in by the contributors: hence the abstracts have been abolished and the summary alone retained. The change is a useful one, placing more space at the disposal of the editor and embarrassing the reader less. At the same time we regret the absence of references to

the papers themselves, which might be added as footnotes, or incorporated in the text; and perhaps more distinction might be drawn between the longer researches, or more valuable memoirs of the year, and mere passing scientific observations. However, it is easier to criticise than to compile a work like the one before us. Our readers will form some idea of the comprehensive nature of this "annual record" by the following summary of its table of contents:—Astronomy, together with reports of the American observatories, contributed by Mr. Holden, of the United States Naval Observatory, Washington. Physics of the globe, followed by general physics, written by Prof. Barber, who also contributes the next section on chemistry. Mineralogy by Dr. Dana, and geology by Dr. Sterry Hunt. Hydrography and geography follow, the geography of North America being specially full. Microscopy, anthropology, zoology, and botany are contributed by able men in each department. Agriculture, engineering, technology, and industrial statistics are less full, and some of the abstracts given in technology would, we think, have found a better place under the head of physics, such, for example, as the telephone, phonograph, &c.

The observatory reports are a feature of the present volume, information being given concerning the *personnel* of each observatory, its principal instruments, the subjects of special observation during the past year, and those to be taken up during the coming year, and lastly the principal publications emanating from each observatory during the past year.

The bibliography at the end of the annual, giving the list of works on science published during 1877, seems most thoroughly and ably done, and so also is the index to the whole volume, and the concise and useful necrology of scientific workers. W. F. B.

Choice and Chance. An Elementary Treatise on Permutations, Combinations, and Probability. With 300 exercises. By W. A. Whitworth, M.A. Third edition, revised and enlarged. (Deighton, Bell and Co., Cambridge.)

We have all three editions before us, and so are able to mark the growth of this work, which has been very considerable. The number of pages in the last edition is ten less than that of the second edition, but the volume is much thicker, and much of the matter is in smaller type. The work had already attained the position of a standard one on the subjects of which it treats, and it maintains and even improves its position in the present edition. Here, even in the elementary parts are to be found many propositions of great utility which are not to be met with, so far as we know, in any form elsewhere. We do not mean to say that they are not known to mathematicians, but writers have not introduced them into the text-books. Besides chapters on Permutations and Combinations, we have a chapter on *Distribution*, that is the separation of a series of elements into a series of classes, and one on *Derangements* (if a series of elements have been arranged, or if they have a proper order of their own, and we place them in some other order, we *derange* them). Under the head of *chance* we have a full treatment of that part of Probability which usually finds a place in algebraical treatises. Remarks "On the Disadvantages of Gambling," which formed an appendix to the last edition, here forms part of a chapter which also has a few paragraphs to show that insurance is the reverse of gambling, and discusses the effect of the repetition first of a fair wager, secondly of a wager at odds, thirdly of a fair wager on a scale proportioned to the speculator's means, the general case of a lottery with prizes of different value, and closes with a fairly exhaustive account of the Petersburg Problem. The novelty of this edition is a chapter on the geometrical representation of chances. We shall hope to see this chapter considerably enlarged in a future edition. The whole treatment may be said to assume nothing but what a well-primed algebraical student should be able to master. What is much wanted is a general treatise on the subject of Probability for English students. Mr. Todhunter's history of the theory down to the time of Laplace is a most interesting and able one, but it does not fill up the gap. In this branch, as in many others, we are dependent upon French writers, and still must have recourse to the works of Laplace, Poisson, and Liagre.

Pine Plantations on the Sand-Wastes of France. Compiled by John Croumbie Brown, LL.D., &c., &c. (Edinburgh: Oliver and Boyd. London: Simpkin Marshall and Co., 1878.)

The subject of the reclamation of sand-wastes by the planting of coniferous trees or of grasses, shrubs, or other plants is one always of much importance. The extension of pine plantations has a two-fold interest over and above the primary cause of planting, namely, that arising from the general improvement in the appearance of the country, as the plants make growth and develop themselves into goodly forms, and that which is more utilitarian, but withal equally important—in the production of timber. Anything that can be done towards reducing the desolation of these French sand-wastes is a point gained not only, as Dr. Brown points out, for the benefit of France herself, but as indicating that what has been accomplished there may also legitimately be expected elsewhere, "not necessarily by the same means, but by means as appropriate, if they can be discovered." As will be seen from the title, the book does not claim originality, it professes to be a compilation, and the copious extracts, with the usual inverted commas, extending often over continuous pages makes this announcement unnecessary. Nevertheless a good work has been done in bringing together in a convenient form a great deal of valuable matter, scattered about in various books inaccessible for the most part to readers for whom the present work is intended, and amongst whom it will, no doubt, chiefly circulate; containing as it does detailed information on every branch of coniferous culture, from a consideration of the soils most suitable to satisfactory culture, to the collecting of the resin, and other economic products, and the diseases and injurious influences to which the plants are subject.

From the range of country under consideration, it will be understood that the pines treated of are limited to very few species, such as *Pinus sylvestris*, *P. maritima*, and *P. pinaster*. J. R. J.

La Morfologia vegetale. Esposta da T. Caruel. (Pisa, 1878.)

A new text-book of vegetable morphology, characterised by freshness both in the mode of treatment and in the illustrations, is an acquisition to botanical literature, even though written in a language which is unfortunately not familiar to most English readers. Prof. Caruel starts with the primary classification of all vegetable structures into the thallus, which displays no external differentiation, and the cormus, consisting of a central stipes (caulome), to which are attached appendages (phyllomes) more or less differing from the stipes. Under the head of the thallus he then discusses propaguli (of Muscineæ), conidia, sporidia (including zoospores), sporules (or spores, properly so-called), the pollen, and phytozoa (or spermatozoids). The general description of the cormus leads to an account of the various special forms which it assumes, viz., to the morphology of flowering plants and vascular cryptogams; and to the various modes of the reproduction of cormophytes by a process of impregnation, that is, the union of the contents of two dissimilar cells. Finally, Prof. Caruel discusses the various subjects connected with the genesis of species, and concludes with the

system of classification of the vegetable kingdom, an outline of which we have already given to our readers (vol. xviii. p. 646). The author brings to his work a mind trained to great accuracy in the use of terms and in the perception of morphological homologies. Great advantage would ensue by the introduction into vegetable morphology in this country of a similar scientific terminology. A. W. B.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to ensure the appearance even of communications containing interesting and novel facts.*]

American Exploration [1]

North-western Wyoming and Yellowstone Park

DURING a portion of the period 1870-4, the writer was engaged in service as military engineer of the staff of the troops serving in the geographical department of the Platte, U.S.A. This business involved the accumulation of local geographical information for the use of the troops who were constantly in contact with hostile Indians. The most troublesome of these were the Sioux, whose prowess in battle has since been shown to the world in the story of the battle of the Little Big Horn—the Custer massacre.

Within the limits of this department were several dark spots on the map marked "unexplored." One of these was the north-western corner of Wyoming territory—a region of vital interest to geographers, comprising, as it did, the crown of the North American continent. There lay, wrapped in impenetrable mystery, the trackless forest country where, in native lore, the Great Spirit evidenced his eternal anger by spouting great columns of water and smoke into the air far above the highest tree-tops, by filling the air with strange rumbling sounds, and Bad Medicine smells; and by flinging the waters of the great river into the bottomless depths of the Cañon of the Yellow Stone. There lay the Lake Beautiful high on the mountain side, from whose borders the Great Spirit puffed great clouds of smoke. There were the strange mountains that no man had ever entered, and whose existence was only indicated on the best maps by a hazy line of feeble *hachures*. Somewhere in that black and forbidding mass of the Unknown Mountains were hidden the secrets of the sources of the Yellowstone, the largest feeder of the Missouri, as well as those of the Columbia and the Snake. They were literally the "Unknown" Mountains. They had been looked at in awe from a few spots on the west and north, and from the south-east by a few travellers whom they had turned back from the glittering prize just as it seemed within their grasp. They were unknown to the Indians who lived on their border, with the exception of a handfull of outcasts from the Crows and Shoshonees, who, driven from all intercourse with their fellows, were obliged to live in the mountains, of which even they had acquired but a limited and uncertain knowledge. Along their eastern border spread out the hunting-grounds beyond compare of the Sioux, Arrapahoes, Cheyennes, and Crows, from whence no white man or peaceful Indian could ever hope to return unless prepared to cope with fearful odds. The mildest geologist on the planet could not have entered that happy hunting-ground without finding his own—without leaving his bones to whiten in a lonely vale and his scalp to decorate the evening entertainment of some untutored child of nature.

In the winter of 1872-73 General Ord, commanding the department, informed me of his desire that what remained of this dark spot in his field of operations should be cleared up, and, if possible, that a passage-way be discovered between the sources of Yellowstone and Wind Rivers. This would give easy access to the recently-discovered Yellowstone Park region, and very much simplify the question of the shipment of supplies to some of the posts in Montana. This was the sole origin and animus of the expedition.

At that time there had been published concerning the Yellowstone Park region the following:—Hayden's "Geological Report of 1871," Barlow and Heap's "Reconnaissance," and Doane's "Narrative." Of these, Hayden's work was a rapid geological reconnaissance not based upon any topographical work worthy of mention; Barlow and Heap were two officers of engineers who made a military reconnaissance, in which astronomical and topographical instruments were used by trained observers; while Doane, also an officer of the army, simply recounted what he saw. It was also known that Hayden had spent the season of 1872 in the immediate Park region, but that he had not examined the country to the southward and eastward of it. Acting upon this information, and such as had come to me through considerable hard service in the neighbouring country, I decided to carry what explorers call a preliminary triangulation from the surveyed region of the Union Pacific Railroad northward into the Yellowstone Park, there connecting with the work of previous explorers. This route would take me through the region infested by hostile Sioux, thence through the unknown mountains from the eastward into the Park, and thence recrossing somewhere in the neighbourhood of the sources of the Yellowstone. I felt satisfied that, with a thoroughly efficient pack-train, this could be accomplished before the early snows rendered the mountains impassable.

The event proved that if those pack mules had not been handled with the utmost skill by the men in charge of them, and had they not had the agility of squirrels, we should have been turned back into a hornet's nest of redskins.

I had no particular intention of reduplicating anybody's work, but if such happened I am very glad of it. In the cause of science a little duplication and reduplication are things not to be sneered at. Dr. Hayden has been at work this very season reduplicating his own work in the Park and mine too, and I do hope and pray, if there be anything erroneous or incomplete in my work, that he may find and point it out. I am not afraid of truth and right, even though it lay me prone in the dust. It would be a pity indeed if, with the sum of $75,000 and upwards at his disposal, with an outfit that has been the growth of so many years of his own and other people's experience, and with the only dangerous Indians in the whole region completely quiescent and humbled to the dust—it would be a pity indeed if the sum of our knowledge of that wonderful region were not very largely increased and many former errors discovered.

Exploring is at best imperfect work, so far as the survey, which is its foundation feature, is concerned. Observations for longitude with any known portable instruments are painfully erratic unless there be abundant time; angles taken with a light shaky transit in a gale of wind from the summit of one mountain to the most pointed aspects of the summits of others in sight must make some very "holey" triangles; and yet this is the best that has been done or can be done unless there be time and money for a regular survey.

With such an expedition as mine it would have been a sad pity not to give trained scientists an opportunity to gather some of the treasures in our path, and so after careful selection and the advice of one of the most competent scientists in the country (Prof. O. C. Marsh), I took with me some specialist observers. They were excellent hard-working men, and have every reason for being proud of their work. The sum of money placed at my disposal for the work was $8,000.

Prof. Geikie has, I fear, been misled by the one-sided Report of a Congressional Committee.[1] This Report does not afford a fair idea of the issues with which it deals. It conveys the impression that the Engineer Department of the army had been making efforts to absorb the Hayden survey. I was at that time in a position to know that such was not the case.

It may be well to add that both by law and long-continued practice, a portion of the duties of the engineers of the American army comprises public explorations and surveys, and they have always given the greatest possible assistance to specialist observers, who can always do very much more and better work when they have no cares other than those of observation and reflection.

Of Dr. Hayden I would like to say that few men deserve more commendation for successful labour than he. Where others had always failed, he had succeeded in securing from Congress

[1] See NATURE, vol. xviii. p. 315.

[1] House Doc. Report 612, 43rd Cong. 1st Session.

annual appropriations of about $75,000. I know him to be an indomitable worker in the field, and well remember the day when his annual arrival in our department was hailed with the greatest interest, and was the signal for every possible act of kindness and assistance from one end of the command to the other.

Prof. Geikie's quotation, that the presence of an armed escort needlessly irritated the hostile Indians, is out of the pale of decent characterisation. In those days army men were of the opinion that no party having less than 100 long-range breech-loading rifles could safely pass into certain portions of the Sioux country, and that minimum-sized parties could just about take care of themselves on the defensive. That was the basis upon which my party was organised. That there was some error in this judgment was shown by the Custer massacre not long after. To the other portion of the quotation, that the geologists of the Interior Department were never molested by Indians, I will state, from personal knowledge, that they have always taken the most precious care not to operate in the neighbourhood of dangerous Indians, a very sensible proceeding for parties without armed escort. Through carelessness and lack of knowledge of the system of guarding camps, they have been stampeded once or twice by thieving Indians who were after plunder, but did not dare to kill anybody. This misfortune has recently befallen them in Yellowstone Park, where the commonest precautions would have made it impossible. Their presence alone, without armed escort, seems to have been "irritating to the Indians."

Geological Climate and Geological Time

I HAVE been much interested in Prof. Haughton's communication to NATURE, vol. xviii. p. 266, on the subject of geological climate and geological time. I fully agree with him that geological climates cannot be explained by any change in the position of the poles, even supposing such change possible, and for the reason assigned by him, viz., that we have no palæontological evidence of an arctic climate in any portion of the earth in any geological period previous to the glacial. But I have some objections to make to the data on which he bases his estimates of time, and therefore to his views as to the *cause* of geological climates.

I. He supposes aqueous agencies to commence operation, and therefore the archæan (azoic) era to commence when the earth surface had cooled to 212° F., evidently because, as he thinks, water could not exist as a liquid on the earth's surface at a higher temperature. But the writer forgets that with all the water of the ocean in the air as vapour, and the large quantity of carbonic acid now existing in the form of carbon and the carbonates also in the air, the pressure of the primeval atmosphere must have been many times—perhaps several hundred times—greater than now, and the boiling, or rather precipitating, point of water very much higher than 212°.

II. Again: Even with a surface temperature from internal causes of 212°, the crust of the earth must have been *very thin*, not more than 40–50 ft. (for increased atmospheric pressure, though greatly affecting the boiling-point of water, would not sensibly affect the fusing-point of rocks). Under these conditions—by the law of equilibrium—the inequalities constituting land-surfaces and ocean-bottoms could not possibly exist; the ocean would be universal, and therefore there would be no erosion and sedimentation. Therefore when dry land first appeared and erosive agencies commenced to act at the beginning of the azoic era, the surface temperature from internal causes must have been much less than 212°. For my part I believe that this temperature had already become very small, the surface had become substantially cool, and the crust very thick before land could exist, and the history recorded in stratified rocks could commence.

III. Therefore, though I agree with Prof. Haughton that all the evidence we have indicates uniform climates in early geological times, I would not, like him, attribute this to warm decrease of surface temperature from *internal* causes alone. I would attribute it almost wholly to *external* causes. Among these are:—1. The *constitution of the atmosphere*. The greater amount of carbonic acid and water in the atmosphere would shut in and accumulate the sun's heat on the earth surface according to the principle discovered by Tyndall, and applied to the explanation of geological climates by Sterry Hunt. 2. It is probable that the *heat received from the sun* was much greater then than now; for the sun is now cooling, and has been cooling throughout all geological times much faster than the earth. 3. The idea of Poisson, that in the journey of our system through the stellar universe it may be *now* in a region in which the *heat received from space* is exceptionally small, has been, perhaps, too much neglected in these speculations concerning geological climates. 4. The more *uniform distribution* of this greater surface-temperature from any or all these causes, would of course still farther increase the temperature of *high latitudes*. This more uniform distribution might be due to the position and shape of land masses, or to the less area and the less height of the then lands.

IV. Lastly: I think that a little reflection will show that while it may be allowable to roughly estimate the *relative lengths* of different *eras* by the *relative extreme thickness* of their strata; it will not at all do to estimate the *absolute length of geological times by the extreme thickness of all the strata*. For as the *measuring rod* is not the rate at which sediments are now accumulating at any one place, but the *average rate* over the whole bottom of the sea, so *the thing to be measured* is not the extreme thickness of the strata at any one place, much less the extreme thicknesses of different formations in different places piled one atop the other, but the *average thickness of the strata* over the whole earth surface.

Most of the points brought out here have already been discussed by me in my recently published "Elements of Geology."

JOSEPH LE CONTE

University of California, October 2

The Magnetic Storm of May 14, 1878

I WAS much interested in Mr. Perry's note inserted in NATURE, vol. xviii. p. 617, showing the simultaneity of the magnetic storm of May 14, 1878, in different parts of the earth's surface. As these magnetic disturbances are always accompanied by electric disturbances (earth currents) in telegraph wires, I was anxious to find out what effects were observed upon our wires in England on the same day, viz., May 14. I append an extract from the diary of the Relay Station at Haverfordwest, a very important station on the wires running from London to Valentia, and where very careful observations are made of all interferences with the regularity of the working of the wires:—

May 14.

P.M.

6.40.—First appearance of relays not closing automatic switch well on down side of 202.

7.10.—London finds some difficulty in reading on 199; no cause visible here.

7.40.—Up side of automatic switch on 202 rather unsteady.

9.0. —Variations in London's current on 200.

9.10.—Strong positive deflections (earth currents) on Cork wires.

9.15.—Cork complains of marks missing and running; no doubt the result of deflections.

9.30.—Great difficulty with automatic switches on Cork wires owing to continuous strong positive deflections which tend to opening of switches when battery currents are in opposite directions, and to close them when in same direction. Probably earth-currents influenced them earlier in evening.

9.40.—Deflections diminishing; wires going better.

9.45.—Deflections ceased.

10.0. —All wires going well; weather wet.

10.10.—*Aurora Borealis visible about this time.*

11.25.—Earth currents very strong again on all wires, causing much trouble with automatic switches. Almost full deflection on up side of 201 and 202.

10.40.—Deflection on 202 reversed, and not so strong as before.

10.45.—Full deflection on up side of 202.

10.48.—Deflection on 199 causes up automatic switch to remain depressed.

MIDN.—Earth currents disappearing.

May 15.

A.M.

12.40.—Electric storm seems to have spent itself. Weather fine; clear moonlit sky.

May 15.
A.M.
1.15.—Weather wet. High winds coming on.
7.0. —Nearly six hours' rain and wind.

The numbers 199, 200, 201, and 202 are those of the wires.

Mr. Ellis has also told us (p. 641) of what was observed at Greenwich. Although the magnetic disturbance commenced about 6 P.M. at Greenwich, it only reached a maximum at 9 P.M., when the electric disturbances were observed at Haverfordwest, though indifferent working, most probably due to them, commenced at 6.40. At 11.45 P.M. the north end of the needle at Greenwich moved sharply westward, and about the same time the currents were reversed at Haverfordwest. From midnight to 12.40 A.M. the currents gradually disappeared. Earth currents were also active at Greenwich, as indeed they were everywhere. Unfortunately the wires at the post-office were so fully occupied with press work during these hours, that no observations could be taken. It will be noticed that the aurora borealis was observed. W. H. PREECE

October 21

Giddiness

A TRUE theory of the cause of giddiness ought to explain the following extreme experience, which deserves record in print. The method was first told to me by a friend; I once tried it myself successfully in a mitigated form, and will assuredly not repeat the experiment, and I persuaded a philosophical friend to try it also, with much the same result. Stand in the middle of a soft field where you can't hurt yourself by tumbling on the ground or against anything; avoid having your best clothes on, and secure appreciative spectators. Then put both hands one above the other on the top of your umbrella or walking-stick, and bend down until your forehead rests on the back of your hands. Thus your legs will be vertical, your body will be more or less horizontal, and the umbrella will be vertical. Shut your eyes. Then get a friend, by touching your hips, so to guide you that you shall circle three times, with a sidelong gait, round the vertical umbrella as an axis. Finally raise your head quickly, and try to walk straight as though nothing particular had happened. What will occur is a frightful giddiness and feeling of sickness, a sense of the ground rising up tumultuously on all sides, a wild rush to save yourself, and a headlong tumble.

F. G.

OUR ASTRONOMICAL COLUMN

THE SATURNIAN SATELLITE HYPERION.—In a letter from Prof. Asaph Hall it is remarked that the ephemeris for September last, given in NATURE, requires correction by nearly two days, although it was deduced from the elements which he showed to closely represent the Washington observations in 1875 and 1876 (*Astron. Nach.*, No. 2,137). There appear to be great difficulties attending the satisfactory determination of the orbit of this satellite, doubtless arising in the main from the magnitude of the perturbations with which its motion is affected, but for this reason it is the more necessary that it should be regularly observed, and a rough indication of the position of so extremely faint an object is better than none.

If we take for a peri-saturnium passage September 24·8393 G.M.T. with Prof. Hall's other elements, the calculated and observed distances on September 27 agree, and the computed angle is one degree in excess of observation. On the same system the following angles and distances are found for 10h. G.M.T.:—

	Angle.	Distance.		Angle.	Distance.
	°	″		°	″
Oct. 25	271	137	Nov. 1	95	217
,, 26	268	82	,, 2	94	225
,, 27	250	23	,, 3	94	211
,, 28	107	41	,, 4	93	175
,, 29	99	99	,, 5	92	119
,, 30	97	150	,, 6	87	49
,, 31	96	191	,, 7	287	29

THE MEAN PARALLAX OF A STAR OF FIRST MAGNITUDE.—Prof. Gylden, director of the Observatory at Stockholm, has reported the result of a preliminary calculation bearing upon the mean distance of a star of the first magnitude. Remarking that in the actual state of our knowledge, when a general result is to be deduced from the parallaxes so far measured, we must not only take into account the apparent brightness of the stars concerned, but also their apparent proper motions, since the magnitude of the proper motion is to be viewed as at least as sure a criterion of a measurable parallax as the apparent brightness; as a hypothesis, it is then assumed that the actual parallax p of a star of nth magnitude with the apparent motion s, will be given by the formula

$$p = P \frac{s}{\sigma_n M_n}$$

where σ_n signifies the mean apparent motion of a star of nth magnitude and M_n the distance estimated according to its brightness. P is a constant, which for $M = 1$ indicates the mean parallax of a star of the first magnitude.

Prof. Gylden takes the following data, depending upon observation, for sixteen stars, of which the parallaxes are supposed to be known with the greatest degree of approximation:—

	mag.	p	s
		″	″
α Centauri	1	0·900	3·674
61 Cygni	5	0·511	5·221
L. 21185	7	0·501	4·734
34 Groombr.	8	0·307	2·801
L. 21258	8·5	0·260	4·403
Oelt. 17415	9·5	0·247	1·200
σ Draconis	5	0·222	1·925
Sirius	1	0·193	1·252
70 Ophiuchi	4	0·162	1·108
α Lyræ	1	0·153	0·349
1830 Gr.	7	0·147	7·053
ι Urs. maj.	3	0·133	0·525
α Bootis	1	0·127	2·258
γ Draconis	2	0·092	0·063
α Aurigæ	1	0·046	0·438
α Urs. min.	2	0·046	0·045

From the adopted values of p, s, together with the products $\sigma_n M_n$, 16 equations of condition can be formed, the solution of which by the method of least squares will furnish the value of P. But Prof. Gylden points out that this mode of treatment will not be found to answer the object in view, since the determination of the weights of the different equations, which can in no wise be considered equal, is attended with great difficulties. On the assumption of equal weight, the value of P comes out, 0″·048. As another mode of treatment, normal equations may be formed in various ways, each containing the unknown quantity P, and consequently each serving for a determination of the quantity sought. The sum of all the equations thus obtained gave P = 0″·062.

This value, however, is greatly influenced by several stars of the first magnitude with large proper motion. Omitting α Centauri, α Bootis, and Sirius, the remainder give P = 0″·086, or if all stars of the first magnitude are omitted, P = 0″·083. Again, if all stars with extreme motions are neglected, and a value of P derived from the nine stars which remain, with proper motions less than 2″ annually, it is found to be 0″·084. Prof. Gylden considers that the near agreement of values obtained from these two calculations, in which the extreme case of brightness and motion enter, affords some support to the inference that the relation indicated by the above formula between parallax, apparent motion, and apparent brightness may be taken as an approximation to the truth. It may be remarked that Prof. Peters found for the mean parallax of a first-magnitude star, 0″·102 ± 0″·026; the new value is within the limit of his probable error.

ON THE TIDES OF THE SOUTHERN HEMISPHERE AND OF THE MEDITERRANEAN[1]

On the coasts of the British Islands and generally on the European coasts of the North Atlantic and throughout the North Sea, the tides present in their main features an exceptional simplicity, two almost equally high high-waters and two almost equally low low-waters in the twenty-four hours, with the *regular* fortnightly inequality of spring tides and neap tides due to the alternately conspiring and opposing actions of the moon and sun, and with large *irregular* variations produced by wind. Careful observation detects a small "diurnal" inequality, (so called because it is due to tidal constituents having periods approximately equal to twenty-four hours lunar or solar) of which the most obvious manifestation is a difference at certain times of the month and of the year between the heights of the two high-waters of the twenty-four hours, and at intermediate times a difference between the heights of the two low-waters.

In the western part of the North Atlantic and in the North Sea, this diurnal inequality is so small in comparison with the familiar twelve-hourly or "semi-diurnal" tides that it is practically disregarded, and its very existence is scarcely a part of practical knowledge of the subject; but it is not so in other seas. There is probably no other *great* area of sea throughout which the diurnal tides are practically imperceptible and the semi-diurnal tides alone practically perceptible. In some places in the Pacific and in the China Sea it has long been remarked that there is but one high water in the twenty-four hours at certain times of the month, and in the Pacific, the China Sea, the Indian Ocean, the West Indies, and very generally wherever tides are known at all practically, except on the ocean coasts of Europe, they are known to be not "regular" according to the simple European rule, but to be complicated by large differences between the heights of consecutive high-waters and of consecutive low-waters, and by marked inequalities of the successive intervals of time between high-water and low-water.

On the coasts of the Mediterranean generally the tides are so small as to be not perceptible to ordinary observation, and nothing therefore has been hitherto generally known regarding their character. But a first case of application of the harmonic analysis to the accurate continuous register of a self-recording tide-gauge (published in the 1876 Report of the B.A. Tidal Committee) has shown for Toulon a diurnal tide amounting on an average of ordinary midsummer and mid-winter full and new moons to nearly $\frac{4}{5}$ of the semi-diurnal tides; and the present communication contains the results of analysis showing a similar result for Marseilles; but on the other hand for Malta, a diurnal tide (similarly reckoned), amounting to only $\frac{1}{4\frac{1}{2}}$ of the semi-diurnal tide. The semi-diurnal tide is nearly the same amount in the three places, being at full and new moon, about seven inches rise and fall.

The present investigation commenced in the Tidal Department of the Hydrographic Office, under the charge of Staff-Commander Harris, R.N., with an examination and careful practical analysis of a case greatly complicated by the diurnal inequality presented by tidal observations which had been made at Fremantle, Western Australia, in 1873-74, chiefly by Staff-Commander Archdeacon, R.N., the officer in charge of the Admiralty Survey of that Colony. The results disclosed very remarkable complications, the diurnal tides predominating over the semi-diurnal tides at some seasons of month and year, and at others almost disappearing and leaving only a small semi-diurnal tide of less than a foot rise and fall. These observations were also very interesting in respect to the great differences of mean level which they showed for different times of year, so great that the low-waters in March and April were generally higher than the high-waters in September and October. The observations were afterwards, under the direction of Capt. Evans and Sir William Thomson, submitted to a complete harmonic analysis worked out by Mr. E. Roberts. Not only on account of the interesting features presented by this first case of analysis of tides of the southern hemisphere, but because the south circumpolar ocean has been looked to on theoretical grounds as the origin of the tides, or of a large part of the tides, of the rest of the world, it seemed desirable to extend the investigation to other places of the southern hemisphere for which there are available data. Accordingly the records in the Hydrographic Office of tidal observations from all parts of the world were searched, but besides those of Fremantle, nothing from the southern hemisphere was found sufficiently complete for the harmonic analysis except a year's observations of self-registering tide-gauge at Port Louis, Mauritius, and personal observations made at regular hourly, and sometimes half-hourly, intervals for about six months (May to December) of 1842, at Port Louis, Berkeley Sound, East Falkland, under the direction of Sir James Clark Ross. These have been subjected to complete analysis.

So also have twelve months' observations by a self-registering tide-gauge during 1871-2 at Malta, contributed by Admiral Sir A. Cooper Key, K.C.B., F.R.S.

Tide-curves for two more years of Toulon (1847 and 1848) in addition to the one (1853) previously analysed, and for Marseilles for a twelvemonth of 1850-51, supplied by the French Hydrographic Office, have also been subjected to the harmonic analysis.

These results, both for the southern hemishere and the Mediterranean, will form the subject of a paper which Capt. Evans and Sir William Thomson hope to communicate to the Royal Society in the course of the coming session. In the meantime the numbers resulting from the harmonic analysis are submitted without further comments to the British Association for comparison with those for other places in previous Reports of the Tidal Committee. Those of them which represent the most important of the diurnal and semi-diurnal tides are shown in the following table, which includes also for immediate comparison the results for Toulon, 1853.

R in every case denotes, as in previous tables of the British Association Committee, the range of the particular tidal constituent on *either side of mean level;* so that $2R$ is the whole rise *from lowest to highest of the individual constituent.* (In comparing results with those shown in the Admiralty Tide Tables, it must be borne in mind that in the latter it is the rise above the level of ordinary low water spring tides that is given as "heights."

ϵ (technically called the epoch) is the angle, reckoned in degrees, through which an arm, revolving uniformly in the period of the particular tide, has to turn till high water of this constituent, from a certain instant or era of reckoning defined for each constituent as follows:—

Definition of ϵ.[1]

To explain the meaning of the values of ϵ given in the following table of results, it is convenient to use Laplace's "astres fictifs," or ideal stars. Let them be as follows:—

M the "mean moon."

[1] Abstract of paper by Capt. Evans, R.N., F.R.S., and Sir William Thomson, LL.D., F.R.S., read in Section E of the Dublin meeting of the British Association.

[1] This definition for the several cases of K diurnal, and O, P, Q, and L differs by 90°, or 180°, or 270° from the definition given in the British Association 1876 Report for a reason obvious on inspection of Tables I. and II., pp. 304 and 305 of that report, which (except in respect to the longitudes of perigee and perihelion) show ϵ as previously reckoned for the several constituents.

S the "mean sun."
K for diurnal tide, a star whose right ascension is 90°.
K for semi-diurnal tide, the "first point of Aries," or ♈.
O a point moving with angular velocity 2σ, and having 270° of right ascension when *M* is in ♈.
Q a point moving with angular velocity $2\sigma - \varpi$, and 270° before *M* in right ascension when the longitude of *M* is half the longitude of the perigee.

P a point moving with angular velocity, 2η having 270° of right ascension when *S* is in ♈.
N a point moving with angular velocity, $\frac{3}{2}\sigma - \frac{1}{2}\varpi$, and passing alternately through the perigee and apogee of the moon's orbit when *M* is in perigee.
L a point moving with angular velocity, $\frac{1}{2}\sigma + \frac{1}{2}\varpi$, and passing alternately through 90° on either side of the perigee of the moon's orbit when *M* is in perigee.

The value of ϵ in each case above means the number of 360ths of its period which the corresponding tidal constituent has still to execute till its high-water from the instant when the ideal star crosses the meridian of the place. Thus if n denote the periodic speed of the particular tide in degrees per mean solar hour; its time of high-water is $\frac{\epsilon}{n}$, reckoned in mean solar hours after the transit of the ideal star.

In this definition, and in the table of results, the following notation is employed[1]:—

I to denote the mean inclination of the moon's orbit to the earth's equator during the time of the series of tidal observations included in each instance.
ν „ „ the mean right ascension of the ascending node of the moon's orbit on the earth's equator during the same time.
γ „ „ the angular velocity of the earth's rotation.
σ „ „ the mean angular velocity of the moon's revolution round the earth.
η „ „ the mean angular velocity of the earth round the sun.
ϖ „ „ the angular velocity of the progression of the moon's perigee.

"Speed" means the angular velocity of an arm revolving uniformly in the period of any particular tidal constituent; each angular velocity being reckoned in degrees per mean solar hour.

THE PHYSICAL FUNCTIONS OF LEAVES

An elaborate study on the above subject has lately been published by Prof. J. Boussingault, of Paris, in the *Annales de Chimie et de Physique* (vol. xiii. pp. 289-394); in which the phenomena of absorption and transpiration by leaves are treated at great length. Since the memorable experiments of Hales in 1727, recounted in his work on "Vegetable Statics," this branch of vegetable physiology has been rarely touched, and the carefully recorded observations of Boussingault. carried out with the best of modern scientific appliances, possess an unusual value.

The first point studied was the loss of water by transpiration from the leaves of plants under normal circumstances. For this purpose a healthy Jerusalem artichoke (*Helianthus tuberosus*) in a roomy flower-pot was chosen. The top of the pot was covered with a sheet of india-rubber, tightly inclosing the stem of the plant, and provided with an opening for the admission of water. The whole was then weighed, and the loss noted which ensued under various circumstances, by evaporation of water from the leaves, the plant receiving during the experiment weighed normal amounts of water. The total surface of the leaves of the plant (both upper and lower sides) was carefully estimated, and the result reckoned on the square metre. The averages of fourteen experiments showed that the artichoke lost hourly, for every square metre of foliage, the following amounts of water:—in the sunshine sixty-five grammes, in the shade eight grammes, during the night three grammes.

In the next place the question was investigated whether the absorption of water by plants, and the ascent of the sap is due to the force resulting from the transpiration on the surface of the leaves, or whether the roots exercise also a certain amount of force to this end. For this purpose experiments similar to the above were carried out with various plants, firstly under normal circumstances, secondly with the stem minus the roots immersed in water. As an instance we can take mint. The plant with roots showed an hourly evaporation per metre, of eighty-two grammes in the sunshine, and thirty-six in the shade. Under the same condition, without roots, the evaporation was sixteen and fifteen grammes respectively.

[1] The values of I and ν are given to facilitate comparison with the equilibrium values of the several tidal constituents, according to Tables I. and II. of the British Association Tidal Committee's Report of 1876.

The results show that the absorption of water by plants is determined in a great measure by the transpiration occurring in the leaves, that this is maintained for a certain length of time without the assistance of the roots, but cannot continue long, being dependent on the injective power possessed by the roots. The effects of pressure on the absorption was next examined, and it was found possible by this means for a time in certain cases to even more than replace the water lost by transpiration. For example: a chestnut branch dipped in water was found to transpire hourly per metre of foliage, 16 grammes. It was then inserted into a tube of water, and subjected to the pressure of a column of water $2\frac{1}{2}$ metres high. Under these conditions the evaporation mounted to 55 grammes per hour, and the branch at the end of five hours weighed more than at the commencement.

The general result of these experiments shows the mutual working of the various parts of the plant with reference to the phenomena of transpiration. The roots absorbing water from the soil by endosmose, direct it towards the stem. Whether the motive force here is injection by the roots or absorption resulting from the transpiration in the green parts of the plant, or a union of both, is a question still unsettled. The stem serves not only as a passage for the water to reach the leaves, but also as a reservoir to be drawn on during rapid evaporation. In the leaves the sap is concentrated by the transpiration, and the matters in solution enter into the cell formation, or, changed by the action of light, are distributed throughout the plant by the descending sap. The circulation would be quite similar to that in an animal, were it not for the irregularity. While the supply of water from the roots varies but slightly, the loss by evaporation from the leaves is subject to the greatest fluctuations, according to the temperature and hygroscopic condition of the surrounding air. During these periods the leaves draw on their stock of constitution water and the supply in the stem; and when both fail, the phenomenon of wilting ensues.

Numerous experiments were made on the difference in *evaporation during the day and during the night*. Those carried out with leaves of the grape vine gave the following hourly averages per square metre of foliage; in sunshine, 35 grammes; in shade, 11; during the night, 0·5. The trellis on which the vine was trained was 1 metre high and 38 metres long, and presented a surface of 138 square metres of foliage. In sunny weather this would lose by evaporation in the course of 24 hours, 48 kilogrammes of water, and nearly half of that amount during cloudy weather. To give an idea of the enormous amount of aqueous vapour dissipated by plants in the sunshine, calculation showed that an acre of beets could lose in the course of 24 hours between 8,000 and 9,000 kilogrammes. Another experiment made with a chestnut-tree 35 years old showed that it lost over 60 litres of water in the course of 24 hours. The structure of the leaf, however, containing 70-80 per cent. of water, and possessing a thickness frequently of but $\frac{1}{10}$th of a millimetre, would suggest the question why the evaporation is not much more rapid. The answer to this is found in the peculiar structure of the tissue forming the epidermis, designed especially to moderate the transpiration. In order to see the remarkable retentive power exercised by this epidermis, one can expose for a few hours to the sun two cactus leaves of the same superficies, one of which has been deprived of its epidermis. The evaporation in the latter case will be about fifteen times as rapid as in the other. It is the presence of a similar tissue forming the skin of fruits which prevents an otherwise rapid evaporation. For instance, an apple deprived of its skin loses 55 times as much water as a whole specimen in the same time. Losses by rapid evaporation lessen notably the physiological energy of leaves. Thus an oleander leaf containing 60 per cent. of water, when introduced into an atmo-

sphere containing carbonic acid, decomposed 16 c.c. of this gas; one containing 36 per cent. decomposed 11 c.c.; and one containing but 29 per cent. was without action.

A series of observations was made on the relative powers of *evaporation on the upper and lower sides of leaves.* They consisted in plucking two leaves of the same kind at the same moment, covering on the one the upper, on the other the lower side with melted tallow, and then noticing the loss of weight by evaporation in a given time. The average of the results showed that the proportion between the amounts of water evaporated on the upper and lower side of a dozen varieties of leaves was 1 : 4·3. In all cases the amount evaporated from the two exposed sides of two equal leaves was greater than from the entire surface of a similar leaf under the same circumstances.

A point of no small interest with regard to the physical function of leaves is that of their ability to replace the roots of a plant in serving as the agent of absorption. A variety of tests were undertaken to settle this question; among them the following:—A forked branch of lilac (Fig. 1) was so disposed that the one branch was immersed in water while the other was exposed to the ordinary atmospheric conditions. The superficies of foliage was the same on both branches. The transpiration from the surface of the leaves on the latter branch was the same as under normal circumstances, and after the lapse of two weeks the foliage was as fresh as at the commencement, showing that the submerged leaves were fully able to replace the roots in one of their functions. In an experiment with a beet in which one-half of the leaves were in water and one-half in the air, communication being maintained by means of the root, the free portion of the leaves wilted in the course of a day, the neck of the root apparently not offering a sufficient means of communication with the submerged leaves. A grapevine shoot half plunged in water (Fig. 2) maintained a normal evaporation in the free foliage, and remained fresh for over a month. An oleander shoot under similar conditions maintained its normal appearance for four months. With the artichoke it was found necessary that the surface of the leaves beneath the water should be four times that of the leaves above.

FIG. 1.

Closely bordering on this question is another which has excited much dispute, viz., the ability of leaves to draw water from the surrounding air or by immersion, after having suffered losses by transpiration. Prof. Boussingault's numerous experiments show that leaves, after having been exposed to influences causing a rapid evaporation, are able to absorb water rapidly on immersion, and even from an atmosphere saturated with aqueous vapour. There is, however, in both cases no absorption unless the leaves have lost a portion of their water of constitution, *i.e.*, that which is essential to their normal existence. Thus, a wilted branch of periwinkle weighing 4·0 grammes, after remaining in an atmosphere saturated with aqueous vapour for a day and a half, weighed 4·2 grammes, and after twelve hours' immersion in water 9·4 grammes.

The last function of leaves studied by Prof. Boussingault is their ability to absorb solutions of mineral matter, *i.e.*, perform another of the ordinary duties of the roots. For this purpose a solution of gypsum containing $\frac{2}{1000}$ of solid matter was used. Drops of this solution were placed on the leaves of a great variety of plants—under conditions favouring absorption, as in the experiments just described—and protected from evaporation by superincumbent watch-glasses with greased edges (Fig. 3).

FIG. 2

In most instances the drops were absorbed entirely, leaving no traces of the mineral matter; in some cases a slight residue was left, which the addition of a minute quantity of water caused to disappear. As in the case of pure water, the under side of the leaves absorbed much more rapidly than the upper side. Solutions of sulphate and nitrate of potassium gave quite similar results; the absorption of solutions of chloride of sodium and nitrate of ammonium was not so perfect. These results would tend to show that the foliage of a plant is able to supply it with perhaps no small portion of its saline constituents by means of the ammoniacal salts formed in the air, and the alkaline and earthy salts suspended there which are deposited on the surface of the leaves by rain and dew.

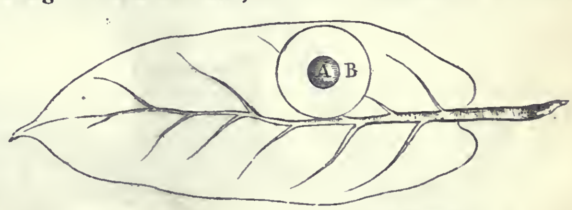

FIG. 3.—A, drop of solution; B, watch glass.

T. H. N.

EDISON'S INVENTIONS

THE fertility of Mr. Edison's inventive genius has frequently been referred to recently, though the attractive and popular nature of the phonograph has had the effect of throwing some almost equally important inventions into the shade. We propose, with the aid of the *Scientific American*, copies of which have been sent us by Mr. Edison, to draw attention to a few of these other inventions; the illustrations which we are able to give have also been kindly sent us by Mr. Edison himself.

Mr. Edison's laboratory, in size and external appearance, resembles a country church. The interior, however, is not so church-like. The first apartment is a reception room, on the right of which is the private office, containing a large library of scientific works. Beyond these there is a large room containing materials and a number of glass cases filled with physical and chemical apparatus.

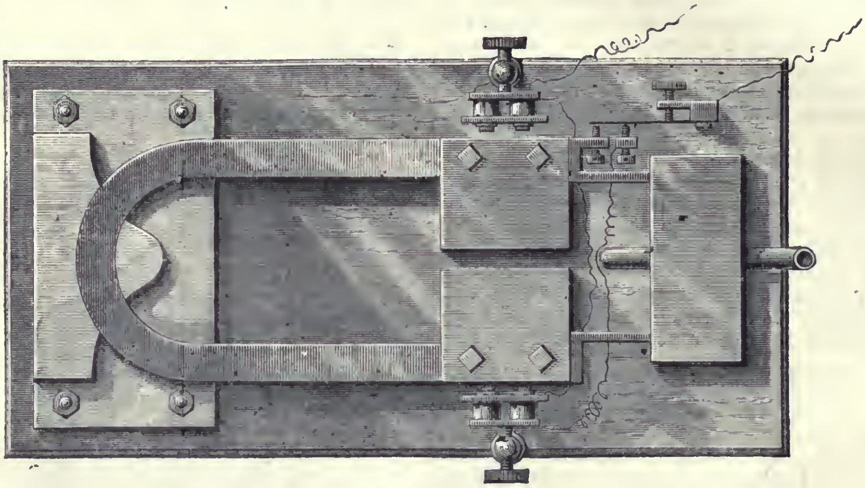

FIG. 1.—Edison's Harmonic Engine.

The machine shop at the rear is furnished with the best of machinery and tools, and is kept constantly in operation in carrying out the plans of Mr. Edison. On the second floor there is a single spacious room, which is the laboratory proper. Here, upon the walls, are shelves which are thickly studded with bottles, jars, and boxes, containing a multitude of substances, both common and rare. It is said to be a chronic habit of Mr. Edison to purchase every newly discovered substance, so that it will be at hand should it be required. Here also is the carbon relay, the progenitor of all existing carbon telephones, "microphones," and other instruments dependent on the changeable conductivity of carbon under a varying pressure.

One of the earlier of Mr. Edison's inventions is the electro-motograph; a telegraphic instrument in which

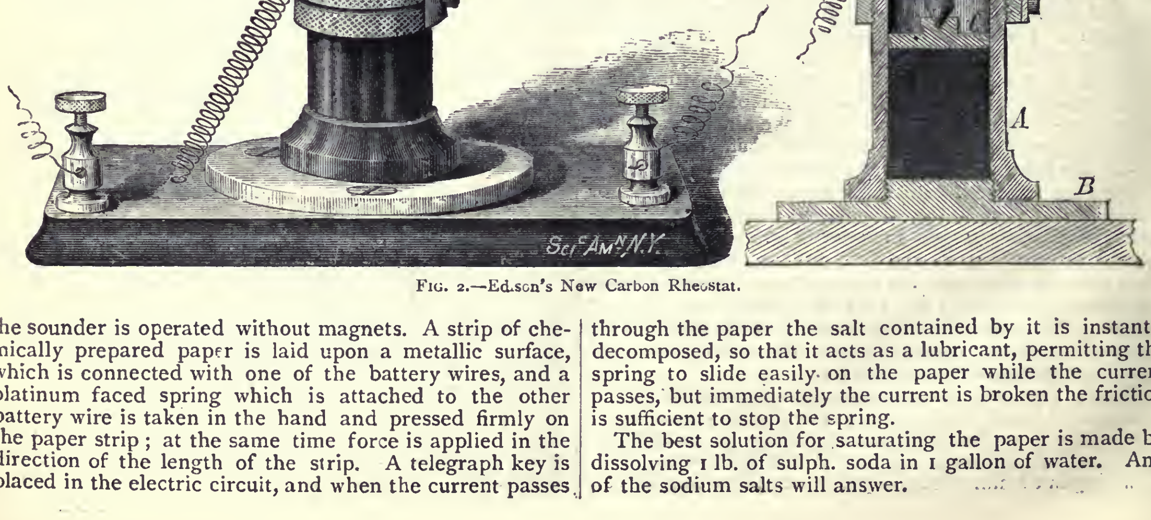

FIG. 2.—Edison's New Carbon Rheostat.

the sounder is operated without magnets. A strip of chemically prepared paper is laid upon a metallic surface, which is connected with one of the battery wires, and a platinum faced spring which is attached to the other battery wire is taken in the hand and pressed firmly on the paper strip; at the same time force is applied in the direction of the length of the strip. A telegraph key is placed in the electric circuit, and when the current passes through the paper the salt contained by it is instantly decomposed, so that it acts as a lubricant, permitting the spring to slide easily on the paper while the current passes, but immediately the current is broken the friction is sufficient to stop the spring.

The best solution for saturating the paper is made by dissolving 1 lb. of sulph. soda in 1 gallon of water. Any of the sodium salts will answer.

Electricity as a motive power, until now, has been a comparative failure, as 90 per cent. of the battery has been wasted. Mr. Edison has devised a novel electrical machine which he calls the harmonic engine, in which 90 per cent. of the power is realised. With two small electro-magnets and three or four small battery cells, sufficient power is generated to drive a sewing machine or pump water for household purposes. This engine, which is represented in Fig. 1, consists of a fork $2\frac{1}{2}$ feet long, made of 2-inch square steel. The curved part of the fork is firmly keyed in a solid casting which is bolted to a suitable foundation, and to each arm of the fork is secured a 35 lb. weight. Outside of and near the end of each arm is placed a very small electro-magnet. These magnets are connected with each other, and with a commutator that is operated by one of the arms. The arms make thirty-five vibrations per second, the amplitude of which is $\frac{1}{8}$ inch. Small arms extend from the fork arms into a box containing a miniature pump having two pistons, one piston being attached to each arm. Each stroke of the pump raises a very small quantity of water, but this is compensated for by the rapidity of the strokes. Mr. Edison proposes to compress air with the harmonic engine, and use it as a motive agent for propelling sewing machines and other light machinery. The power must be taken from the fork arms so as not to affect the synchronism of their vibrations, otherwise the engine will not operate.

In quadruplex telegraphy it is vital to the working of the system to perfectly balance the electrical current. The common method of doing this is to employ a rheostat containing a great length of resistance wire, more or less of which may be thrown into or cut out of the electrical circuit by inserting or withdrawing plugs or keys. This operation often requires thirty minutes or more of time that is or might be very valuable. To remedy this difficulty

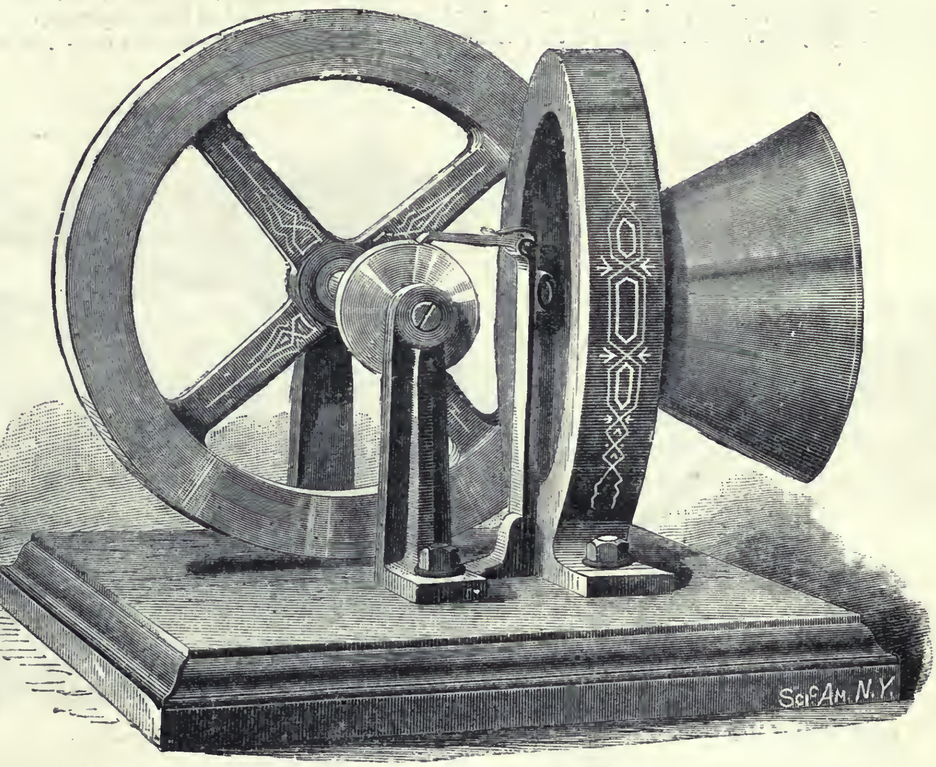

FIG. 3.—Edison's Phonometer.

Mr. Edison has devised the instrument represented in Fig. 2, 1 being a perspective view and 2 a vertical section. A hollow vulcanite cylinder A is screwed on a boss on the brass plate B. Fifty disks—cut from a piece of silk that has been saturated with sizing and well filled with fine plumbago and dried—are placed upon the boss of the plate B, and are surmounted by a plate C, having a central conical cavity in its upper surface. A pointed screw D passes through the cap E at the top of the cylinder A, and projects into the conical cavity in the plate C. The screw is provided with a disk F, having a knife edge periphery which extends to the scale G, and serves as an index to show the degree of compression to which the silk disks are subjected. The instrument is placed in the circuit by connecting the cap E with one end of the battery wire and the plate B with the other end.

The principle of the instrument is identical with that of Mr. Edison's carbon telephone. The compression of the series of disks increases conductivity; a diminution of pressure increases the resistance. Any degree of resistance within the scope of the instrument may be had by turning the screw one way or the other. In this instrument the resistance may be varied from 400 to 6,000 ohms, and any amount of resistance may be had by increasing the number of silk disks.

The thermo-telephone, although at present without special practical value, is certainly a novelty. It consists of a thermopile having placed in its collecting funnel a hard rubber disc. A sound made in front of this disc is heard in a receiving telephone connected with the thermopile.

The *rationale* of this is at once apparent when a strip of hard rubber is placed against the lips and bent, so that the strip will be alternately concave and convex. The difference in temperature is very perceptible, the convex surface being cold and the concave surface warm, and, however rapid the vibrations which render the surfaces alternately convex and concave, the result is the same.

Mr. Edison, in his telephone and phonograph experiments, discovered that the vibrations of the vocal chords were capable of producing considerable mechanical effect. Acting on this hint, he began experiments on a phonometer, or instrument for measuring the mechanical force of sound-waves produced by the human voice. In the course of these experiments he constructed the machine shown in Fig. 3, which exhibits the dynamic force of the voice. The machine has a diaphragm and mouth-piece similar to a phonograph. A spring which is secured to the bed piece rests on a piece of rubber tubing placed against the diaphragm. This spring carries a pawl that acts on a ratchet or roughened wheel on the fly-wheel shaft. A sound made in the mouth-piece creates vibrations in the diaphragm, which are sufficient to propel the fly-wheel with considerable velocity. It requires a surprising amount of pressure on the fly-wheel shaft to stop the machine while a continuous sound is made in the mouth-piece.

The speaking trumpet, which, for two centuries at least, has been employed to direct sound so that it may be heard over a long distance, is much used at sea, and is often employed on land to direct vocal sounds so that they may be heard above other sounds. It is tolerably certain that the speaking trumpet is of modern origin, and that it is the invention of Samuel Moreland, 1670.

Kircher, in his "Ars Magna et Umbra" and in his "Phonurgia," mentions a kind of gigantic speaking-trumpet, described as the horn of Alexander. According to Kircher, this horn enabled Alexander the Great to call his soldiers from a distance of ten miles. The diameter of the ring must have been eight feet, and Kircher conjectures that it was mounted on three poles.

Late in the last century Prof. Huth, a German, made a model of the horn, and found that it served as a powerful speaking-trumpet, but we are considerably in doubt as to the distance through which sounds can be projected through such an instrument.

The ear-trumpet, which is the counterpart of the speaking-trumpet, has been made in various forms during the last two centuries, but no form yet devised has any advantage over a plain conical tube with a bell-shaped or flaring mouth.

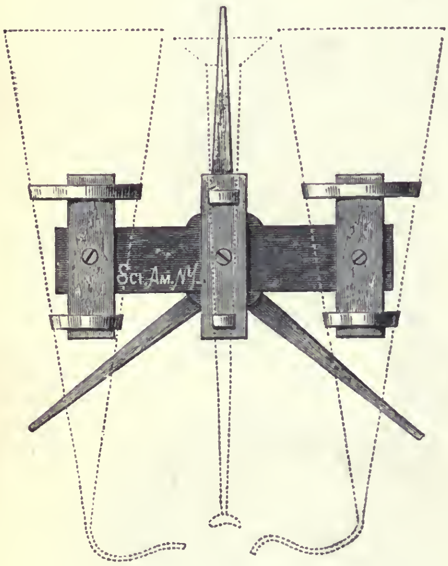

FIG. 4.—Plan of Megaphone.

FIG. 5.—Edison's Megaphone.

Mr. Edison, in his researches on sound, has made many curious experiments, one of the most interesting of which is that of conversing through a distance of $1\frac{1}{2}$ to 2 miles with no other apparatus than a few paper funnels. These funnels constitute the megaphone, an instrument wonderful both for its simplicity and effectiveness. In the plan, Fig. 4, the details of construction are clearly shown, and Fig. 5 represents the instrument as it stands on the balcony of Mr. Edison's laboratory. A mile and a half distant there is another instrument exactly like the one in Fig. 5.

The two larger funnels are 6 feet 8 inches long and $27\frac{1}{2}$ inches in diameter at the larger end. These funnels are each provided with a flexible ear-tube, the end of which is placed in the ear. The speaking-trumpet in the middle does not differ materially from the ordinary ones. It is a little longer and has a larger bell mouth. With this instrument conversation can be readily carried on through a distance of $1\frac{1}{2}$ to 2 miles. A low whisper, uttered without using the speaking-trumpet, is distinctly audible at a thousand feet, and walking through grass and weeds may be heard at a much greater distance.

These statements, it must be understood, are given on the authority of the *Scientific American*, but some experiments lately made with a paper megaphone by Prof. Barrett lend them strong support

COLOUR BLINDNESS IN RELATION TO THE HOMERIC EXPRESSIONS FOR COLOUR

IN an article on "The Colour Sense" in the number of the *Nineteenth Century* for October last, Mr. Gladstone points out certain peculiarities, very remarkable and very difficult to account for, in the expressions for colour used by Homer. "Although," he says, "this writer has used light in its various forms for his purposes with perhaps greater splendour and effect than any other poet, yet the colour adjectives and colour descriptions of the poems are not only imperfect but highly

ambiguous and confused." And again—"We find that his sense of colour was not only narrow, but also vague, and wanting in discrimination."

The article is an expansion of a chapter in the same author's "Studies on Homer and the Homeric Age," published in 1858 (vol. iii. page 457), from which the proposition is quoted; "That Homer's perception of the prismatic colours, or colours of the rainbow, and *à fortiori* of their compounds, were, as a general rule, vague and indeterminate." Mr. Gladstone gives many examples illustrating these opinions, and by powerful and ingenious reasoning, he endeavours to establish from them the general conclusion that "the organ of colour was but partially developed among the Greeks of the heroic age."

I have no intention of disputing this conclusion, in favour of which no doubt much may be said, but I think it may be worth while, on scientific grounds, to point out how remarkably the anomalies and imperfections in question correspond with those that might be expected to arise if the writer were assumed to be *colour blind*.

Mr. Gladstone makes some allusion to the possibility of a defect in the poet's organisation; but it appears to me that, probably from the facts connected with colour blindness not being fully known to him, he hardly gives this point the attention it deserves. In his earlier essay he expresses the opinion that such a supposition "cannot be resorted to, when we bear in mind Homer's intense feeling for form, and when we observe his effective and powerful handling of the ideas of light and dark." From this remark it is clear that Mr. Gladstone was unaware of the fact that colour blindness can, and usually does, coexist with a perfect feeling for form, and with as vivid ideas of light and dark as are possessed by the normal-eyed. In the later article he mentions the defect more specifically, and refers to Prof. Wilson's book on the subject (published in 1855), but he does not add anything to the argument, and appears to leave the point still open to discussion, when further data can be supplied.

In 1856 I presented to the Royal Society a paper on Colour Blindness, which was afterwards published in the *Philosophical Transactions*, vol. 149, p. 323. Its object was to state my own case (which happens to be one of the most decided on record) and to show that the general phenomena attending this defect of vision were more simple, uniform, and consistent than was generally supposed.

Before I wrote that paper the general impression was that, although there were certain broad particulars in which the sensations of different colour-blind patients agreed, yet there were many varieties of the defect, differing much in character as well as in severity, each being denoted by its own peculiar symptoms, and each, therefore, requiring special classification. Prof. Elie Wartmann, of Lausanne, whose paper on the subject was published in England in 1846, held the opinion that there were as many varieties of the defect as of individuals affected with it, so that no classification was possible. Dr. Wilson did not go so far as this, but he considered the cases as varying much in degree, and he inclined strongly to the opinion that the most severe form of the defect was very rare.

To illustrate the great variety of mistakes made by the colour blind, and to show the confusion resulting therefrom, I gave the following list of "symptoms" which had been observed in various patients, and which were all combined in my own case:—

Blue and yellow are always perfectly distinguished, even in their lighter or darker tones, and are never confounded with each other.

Only these two colours are seen in the solar spectrum, the blue corresponding to the more and the yellow to the less refrangible rays. The red space is seen as yellow.

Red, though frequently identified in certain cases, is often confounded with black, white, or grey, with orange, with yellow, with green, with brown, with blue, and with violet. Crimson and pink have no relation to the red of vermilion.

Green is a colour most perplexing to the patient, who cannot be said generally to manifest any definite sensation about it at all. It is confounded not only with red, but also with black, white, or grey, with orange, with yellow, with blue, with violet, and with brown.

Orange is confounded with yellow; violet is confounded with black or grey, and with blue.

No wonder that philosophers should have despaired of finding any reasonably simple diagnosis for such a heterogeneous mass of symptoms; it was, however, my object to show this could be done. By a long and careful study of my own sensations, aided by a masterly suggestion of Sir John Herschel's that had been published shortly before, I found, in the first place, that notwithstanding the apparent variety of the symptoms in different persons, the defect was uniform, or nearly so, in all; and in the second place, that in spite of the apparent complexity of the phenomena, this defect was of a very simple character. I believe the explanations I gave have been generally accepted, and subsequent experience has amply confirmed them.

As few people have a clear understanding what Colour Blindness really means, and as without such an understanding it would be impossible to make my remarks intelligible, I must ask leave to describe the defect as briefly as I can, referring to the *Philosophical Transactions* for fuller details and demonstrations.

In the first place we see white and black, and their intermediate or compound grey (provided they are free from alloy with other colours), precisely as others do.

Secondly, there are two colours properly so called, namely, yellow and blue, which also, if unalloyed, we see, so far as can be ascertained, in the normal manner.

But these two are the *only* colours of which we have any sensation; and hence the defect has been given by Sir John Herschel the scientific name of *dichromic vision*.

But now comes the difficulty of the explanation. It may naturally be asked: Do we not *see* objects of other colours, such as roses, grass, violets, oranges, and so on? And if we do see them, what do they look like? The answer is that we do see all such things, but that they do not give us the colour sensations correctly belonging to them; their colours appear to us varieties of the other colour sensations which we are able to receive.

This will be best explained by examples. Take first the colour red. A soldier's coat or a stick of red sealing-wax conveys to me a very positive sensation of colour, by which I am perfectly able to identify, in a great number of instances, bodies of this hue. If, therefore, the investigation of my experience ended here, there would be no reason to consider me blind to red, or as having any grave defect in my vision regarding it. But when I examine more closely what I really do see, I am obliged to come to the conclusion that the sensation I perceive is not one that I can identify separately, but is simply a modification of one of my other sensations, namely, *yellow*. It is, in fact, a yellow shaded with black or grey—a darkened yellow, or what I may call yellow brown. I find that all the most common hues of red correspond with this description, and in proportion as they are more scarlet or more tending towards orange, the yellow I see is more vivid. The explanation, I suppose, is, that none of such reds are pure, they are combinations of red with yellow; so that I see the yellow element of the combination, while the true red element is invisible to me as a colour, and acts only as a darkening shade.

I obtain a further proof of this by the change of sensation when the hue of red is altered. I find that as the colour approaches crimson the yellow element becomes fainter and the darkening shade more powerful, until very

soon the yellow disappears, and nothing but a grey or colourless hue is presented to my eye, although the colour is still a positive and powerful red to the normal-eyed. So that there is a hue of red which as a colour is absolutely invisible to the colour-blind.

If I go on beyond this point and take reds that pass from crimson towards the hue called lake, I see my other colour come in, a faint blue, which increases till violet is reached, when it becomes more decided.

Violet is understood, I believe, to be a compound of blue with red, and accordingly, the red element being invisible to the colour-blind, violet hues generally appear to them only as darkened blue. There are, however, examples where, from the red being very strong, the blue appears to lose its effect, and the impression given is colourless, black, or grey. They correspond, in fact, with the neutral red before described, although still called violet or purple by the normal-eyed. This latter effect is much enhanced under the artificial light of gas or candles.

A similar explanation will apply to orange, a combination of red and yellow, in which the yellow only is perceived.

The appearance of green to the colour-blind corresponds exactly to that of red; green in its true aspect is invisible to them, and consequently when neutral, *i.e.*, unmixed with any other colour, it presents to their eyes he appearance of grey. When, however, it is mixed with yellow (and most of the greens in nature are yellow greens) they see the yellow only, but diluted or darkened by the invisible green element. And in the less frequent cases where the green is mixed with blue, they see the blue only, in like manner.

It may now easily be understood how it is that so simple a defect of vision gives rise to so complex a series of symptoms as those already described.

Take first the colour red. If it is a scarlet variety, as the majority of reds are, presenting the appearance of yellow to the colour blind, they may naturally confound it with the latter colour, as well as with orange, with yellow green, and with brown, all which cause to them the same sensation. If, on the other hand, the red contains a predominance of blue, it may be confounded, on the same principle, with blue or violet. If it is a neutral red, lying between the two, it will be confounded with black or grey. A pale pink, though very distinctly coloured to the normal-eyed, often offers so little colour to the colour-blind as to be mistaken for white, or very light grey.

The same explanation will apply to green. Its yellow varieties may be confounded with red, orange, yellow, and brown, its blue varieties with blue and violet, and its neutral hue with black or grey, or if very pale, with white.

The confusion of orange with yellow, and of violet with blue, black, and grey, have been already sufficiently explained.

I must now go on to show how the hypothesis of Colour Blindness may serve to explain or account for the anomalies in Homer's descriptions of colour. It is out of my province to meddle with any questions of classical scholarship, I adopt all Mr. Gladstone's critical nterpretations, and I suppose I need not desire a higher authority. It will be convenient to refer to his two essays indiscriminately, using the letter N. for the article in the *Nineteenth Century*, and H. for the chapter in the Studies on Homer.

Before going into any detail I may notice the general classification which Mr. Gladstone (H. 458, &c.) has given of the Homeric peculiarities, and it is impossible not to see, at a glance, how exactly this corresponds with what might be expected from the colour-blind.

I. The paucity of Homer's colours. Excluding black and white, Mr. Gladstone reduces them to four, intimating, however, in the following sentence, that even this number is too many.

The colour-blind list is limited to two.

II. The use of the same word to denote not only different hues or tints of the same colour, but colours which, according to the normal-eyed, are essentially different.

This is the *shibboleth* of the colour-blind defect.

III. The description of the same object under epithets of colour fundamentally disagreeing one from the other.

Mr. Gladstone only names three instances, referring to iron, to the dragon, and to a thunderbolt, none of which appear to me to be very conclusive; but since a colour-blind person may, with perfect correctness according to his own sensations, describe grass as either green, red, orange, or yellow, the defect will amply account for this peculiarity.

IV. The vast predominance of black and white; and

V. The slight use of colour, as compared with other elements of beauty for the purpose of poetic effect, and its absence in certain cases where we might confidently expect to find it.

Nothing can be more natural than this, in the case of a writer to whom the great mass of colours in nature are invisible.

When we go into detail, and review the instances Mr. Gladstone has given of Homer's particular applications of colour adjectives, the correspondence with the colour-blind hypothesis becomes much closer and more conclusive.

As a general preliminary, let us ask what such a writer, if colour-blind, might be expected to do? How would he be likely to use his epithets of colour?

In the first place he would be certain to use them incorrectly, that is, in a way not consistent with the ideas ordinarily attached to them. He must adopt words in ordinary use; but he can form no proper idea of their meaning, and, as the objects they apply to appear under totally different aspects to him, his use of the words must necessarily be confused and often inappropriate. This may be particularly looked for in regard to red and green; terms which, although conveying ideas so positive and unmistakable to the normal-eyed, have to the colour-blind no definite signification at all.

But secondly, there ought to be a certain consistency and intelligibility in his use of the terms when viewed in regard to his own sensations; and if my view of the simple and uniform character of the disease be correct, we ought to be able, knowing what these sensations are, to form a tolerable idea how colour epithets would be applied so as to accord with them.

Omitting all considerations of white, black, or grey, and confining ourselves to colour proper, we know that every coloured object in nature presents to the colour-blind person one of two sensations, either that of yellow or that of blue, modified in tone or shade, as I have described. These are positively distinct from each other, and are never confounded. We therefore ought to expect that the colour-epithets used by such a person should be found capable of being arranged in two groups or classes, one corresponding to the yellow sensation, the other to the blue sensation. The various words in either group may have very different meanings to the normal-eyed, but if they all convey the same sensation to the colour-blind person, he may be expected to use them indiscriminately. And, moreover, he ought never to apply a word belonging to one class or group, to an object belonging to the other group; if he did he would fail in the consistency to his own sensations which I am now insisting on. For example, if a person applied the word "orange," a word belonging to the yellow group, to lapis lazuli, or the violet flower, which, on the colour-blind

hypothesis ought to convey to him the idea of blue, the error, although not appearing worse to the normal-eyed than calling grass red, would be altogether inconsistent with the proper colour-blind sensations, and would prove that such a person had not dichromic vision in the sense here intended.[1]

It may further be remarked that, as the colour-blind person finds the yellow sensation much predominating in what he sees, and as he will have observed that it corresponds to a larger number of ordinary colour-words than the blue sensation, his vocabulary for this group will be naturally more copious than for the opposite one.

William Pole

(*To be continued.*)

[1] Some errors might, however, legitimately arise in the use of the words for red and green, from the fact that some hues of these colours give yellow sensations, while others give blue sensations.

CHEMICAL NOTES

Estimation of Mercury.—Prof. Clark, of Cincinnati, describes (*Ber. d. deutsch. chem. Gesell.* xi. 1,409) an interesting application of electrolytic decomposition for the purposes of analytical chemistry, viz., in the separation and estimation of mercury. The solution of the mercury salt, acidulated with sulphuric acid, is placed in a platinum vessel, connected with the zinc pole of a Bunsen bichromate battery of six cells. A piece of platinum foil in connection with the carbon pole is dipped into the liquid, and the decomposition commences at once. At first a mercurous salt is precipitated. This is reduced gradually, until, in the course of an hour, it is completely changed into the metal, which requires simply to be separated from the solution, washed, dried, and weighed. Similar methods for the estimation of zinc, nickel, and copper have for some years been in use.

Separation of Antimony and Arsenic.—One of the problems in analytical chemistry awaiting solution is a satisfactory separation of arsenic from antimony. In the last number of Liebig's *Annalen* (vol. 192) Prof. Bunsen presents a new method intended to supersede that hitherto employed, which was discovered by him a number of years since, depending on the treatment of the combined sulphides with sulphurous acid. In the new process the sulphides are dissolved in potash and subjected to the action of chlorine. A quantity of a saturated aqueous solution of sulphuretted hydrogen, sufficient to precipitate the antimony, as Sb_2S_5, is then added, and in the filtrate the arsenic acid is precipitated on heating as As_2S_5 by a long-continued stream of H_2S.

Specific Heats of Mercury and Iron.—O. Pettersson and E. Hedelius have recently made careful determinations of the specific heat of mercury and iron in the following manner (*Ofvers. f. Vetensk. Förhandl.*, 37, p. 35):—A piece of wrought iron was heated in an air bath to 26°, and then plunged in baths containing weighed quantities of mercury and water at 0°. The resultant temperatures gave the specific heat of iron as referred, firstly to water, and secondly to mercury, and the division of the first value by the second yielded the specific heat of mercury referred to water. The averages derived from twenty experiments give for the average specific heat of wrought iron between 4° and 27°, 0·10808; and for the specific heat of mercury between 0° and 5°, 0·033266. The authors find that the specific heat of mercury suffers but slight alterations between 0° and 100°.

Latent Heat of Water at Temperatures below 0° C.—O. Pettersson (*Ofvers. f. Vetensk. Förhandl.*, 37, p. 53) has lately determined the latent heat of water at temperatures below 0°. For this purpose thin tubes containing water were placed in a mercury calorimeter, cooled to certain temperatures below 0°, and congelation was induced by the insertion of a snow crystal. The latent heat of water at 0° according to Regnault is 79·25. The results obtained by Pettersson at lower temperatures are as follows: − 2·80°, 77·71; − 4·995°, 76·60; − 6·28°, 75·94; − 6·50°, 76·03; − 6·62°, 75·99; all of them coinciding closely with the estimations of the theoretical formula $\frac{\delta r}{\delta T} = c - h$, where r represents the latent heat of fusion, T the absolute temperature, and $c - h$ the difference between the specific heats of the solid and liquid body. Experiments were likewise made with sea water containing 3·536 per cent. of solid matter, and freezing at − 9°. At this temperature pure water would possess a latent heat of 75; the sea water possessed on the contrary but 54, showing that the above proportion of saline matter was sufficient to cause a diminution of 28 per cent. in the latent heat.

Preparation of Salts of Nitrous Oxide.—In the *Journal* of the Chemical Society (clxxxix.) Mr. A. E. Menké describes some of the above salts. In analysing a sample of cast iron an experiment was made attempting the conversion of the phosphorus contained in it by fusion with nitre and sodium carbonate, into an alkaline phosphate. During the operation a bulky yellow precipitate was obtained which proved to be, not a phosphate, but identical with the body obtained by Dr. Divers in the action of sodium amalgam on sodium nitrate. The analysis of the silver salt gave a mean percentage of 78·09 Ag, agreeing therefore with the formula AgNO, which requires 78·26 per cent. Ag. The salt may also be obtained by the simple fusion of iron filings with nitre, the best heat to employ being that of a charcoal furnace. The analysis of the sodium salt obtained by the fusion of iron filings with sodium nitrate gave numbers closely agreeing with the formula $NaNO + 3H_2O$. The substitution of zinc for iron filings failed to produce the body. On acting on the silver salt with ethyl iodide the silver is converted into iodide, and on fractionating the distillate evidence of the formation of an ethereal salt of low boiling point is obtained.

On Manganese Tetrachloride ($MnCl_4$).—Some doubt still existing with regard to the decomposition of manganese oxides higher than the dioxide MnO_2, Mr. W. Fisher has recently made experiments bearing upon this point. The oxides employed are the sesquioxide, Mn_2O_3, and the red oxide of manganese, Mn_3O_4. The analyses of the liquids obtained by the action of the acid on the different oxides were made by decomposing the freshly-prepared solutions with potassium iodide, and then titrating the amount of iodine liberated in each case with sodium hyposulphite. From his experiments Mr. Fisher finds that the higher oxides when treated with excess of acid give a brown liquid containing a highly chlorinated manganese compound easily resolved into manganous chloride and free chlorine, and on dilution with water yielding manganese binoxide in both instances. The solutions appear to be identical, probably containing $MnCl_4$ in each. Under the conditions of the experiment the corresponding chlorides, Mn_2Cl_6 and Mn_2Cl_8, do not appear to be formed from their corresponding oxides, nor do they appear as products of the partial dechlorination of the tetrachloride. The action of the acid on the two oxides the author considers may be represented by the formulæ—

$$Mn_2O_3 + 6HCl = MnCl_2 + MnCl_4 + 3H_2O,$$
$$Mn_3O_4 + 8HCl = 2MnCl_2 + MnCl_4 + 4H_2O,$$

and as a large excess of acid or alkaline chloride renders $MnCl_4$ more stable, he thinks it probable that this body may exist in a form analogous to chloroplatinic acid.

Spontaneous Ignition of Hydrogen by finely-divided Zinc.—In dissolving zinc in hydrochloric acid P. W. Hofmann has observed explosions on the surface

of the liquid in the vessels employed. These phenomena he describes in a paper in the *Chem. Centr.*, 1878, 351, and explains them by the supposition that the gas in its evolution throws up small portions of zinc, rendered porous by the action of the acid, and that these finely-divided particles coming in contact with the air act like spongy platinum, causing the gaseous mixture to explode. The spontaneous ignition of hydrogen has been observed by others, but no satisfactory explanation has been given of the action.

METEOROLOGICAL NOTES

CAPT. HOFFMEYER has made an original and highly important contribution to our knowledge of the distribution of atmospheric pressure in winter over the North Atlantic, and its influence on the climate of Europe, in the last published number of the *Journal of the Meteorological Society of Austria* (October 15). The contribution takes the form of a rectification of Buchan's isobaric charts for this part of the globe, and, by a most ingenious and able method of investigation, entirely his own, Hoffmeyer conclusively shows that Greenland and Iceland exert a powerful influence on the distribution of atmospheric pressure not hitherto properly recognised, resulting in the mean minimum of pressure being localised distinctly to the south-west of Iceland—a minimum accompanied with two subordinate minima, one in Davis Straits and the other in the Arctic Ocean, mid-way between Jan Mayen and the Lofoden Isles. Four typical charts are also given, showing the actual mean pressure of as many individual winter months, from which it is plain that one or other of these three minima plays the chief roll, the other two being, for the time, subordinate; and that, according as the one or the other of these minima of pressure predominates, so is the character of the weather, as regards its mildness or severity, of the winter of the regions surrounding the North Atlantic, determined.

THE *Report of the Royal Meteorological Institute of Prussia for* 1877 has been received. It is the thirtieth Report, and like all the foregoing Reports, is published by the Royal Statistical Bureau, Berlin, with which the Institute, since its establishment in 1848, has stood in close and uninterrupted connection. Important changes are in contemplation, the most vital of which are the severance of the connection between the Institute and the Statistical Bureau, and the establishment of an independent central direction for meteorology. The Bureau has done a graceful act in presenting with the Report a highly characteristic portrait of the veteran meteorologist and physicist Dove, who has directed the affairs of the Institute since December 9, 1848, and who, by the number and thoroughness of his writings and their breadth of view, deserves of all men to be styled the father of meteorology.

AMONG the separate papers incorporated in this Report is a discussion by Dr. Hellmann of the observations of cloud at Crefeld, being in continuation of the author's researches into the cloud-covering of the sky as influenced by the hour of the day, the season of the year, and geographical situation. The daily maximum occurs at Crefeld, about, or a little before sunrise, from September to April, whereas, from May to August, the maximum is from about 11 A.M. to 3 P.M. The monthly maximum, which holds also for all hours of the day, is December, whilst the month with clearest skies is September. The barometric observations at Berlin for the past thirty years are carefully discussed by Prof. Arndt, from the general results of which it appears that the great summer depression of the barometer which is so characteristic a feature of the climatology of the Europeo-Asiatic Continent, is not shown at Berlin, it being a little to eastwards of Berlin, to which the limits of the western outskirts of this wide-spread barometric depression extend.

THE Dutch Meteorological Institute has issued Wind Charts of the North Atlantic, Series I., including the six months from December to May. The region covered by the charts lies between 51—30° N. lat. and 4—52° W. long., and between 30—8° N. lat., and 13—39° W. long. The frequency of the different winds is graphically shown by radii, the length of each being proportional to the frequency of the particular wind it represents. Instead of grouping the observations into 5° squares and into seasons as has been generally done, Dr. Buys Ballot has presented the facts on the charts for each 1° square and for each month, the object being to lay down the geographical position of the winds of this region, so important to navigators as well as men of science, with the closest approach to truth and least possible admixture of hypothesis.

IN a circular letter addressed to the Permanent Committee on Meteorology, Prof. Hildberandsson invites the co-operation of all meteorologists to the carrying out of a more systematic observation of the upper currents of the atmosphere than has yet been attempted. Hitherto the observation of the upper clouds and the directions in which they march, has been confined to isolated observers whose services were enlisted through the enthusiasm of individual meteorologists. But fragmentary and scattered though the observations have necessarily been, the results fairly deduced from them are of so important a nature from their bearings on the great problem of atmospheric circulation, that we have no hesitation in giving our hearty support to Prof. Hildebrandsson's proposal that the meteorological societies and observatories make observations of the movements of clouds, chiefly of the upper clouds, part and parcel of their regular observations, and that the results regularly appear in their publications.

THE great storm of September 15-16, so widely and so severely felt, deserves to be specially noticed on account of the low barometers accompanying it, which were not only exceptionally low for the season but even exceptionally low for any season of the year. From the observations made at the stations of the Scottish Meteorological Society in the north and north-west it is seen that at Thorshavn, Farö, the barometer at 32° and sea-level fell at 9 P.M. of the 15th to 28·058 inches, being the lowest point to which it fell, and about that time the wind shifted from south-east to north-west. At Stornway the barometer fell to its lowest, 28·400 inches at 7 P.M., or two hours earlier than in Farö; at the same hour it fell to the lowest point, 28·457 inches, at Monach lighthouse, the wind at this time attaining its maximum violence during the storm; at Sandwick to 28·404 at midnight; and at North Unst lighthouse it fell during the night to 28·305 inches. Heavy showers with thunder and lightning and heavy continued rain occurred in the North-west Highlands, nearly an inch of rain falling in less than an hour at Portree on the morning of the 15th, and 10·57 inches at Glenquoich during the six days beginning with the 14th.

GEOGRAPHICAL NOTES

THE Gothenburg *Handels Tidning*, of the 16th inst., contains a telegram from Irkutsk, addressed to Mr. Oscar Dickson by Prof. Nordenskjöld, announcing that he had reached the mouth of the Lena on August 27, after having passed Cape Chelyuskin, without meeting with any noteworthy obstacle from ice, and that the voyage would be continued towards Behring's Straits with the highest hopes of success. It is probable that Prof. Nordenskjöld's anticipations have been by this time realised, that the *Vega* has reached Behring's Straits, and thus successfully accomplished the North-East Passage. News has also arrived that the *Lena*, a small steamer which accompanied the *Vega*, has ascended the

river of the same name, having arrived at the town of Yakutsk on September 22.

DR. GERHARD ROHLFS had finally fixed his departure from Malta for the 20th instant. He will be accompanied by two Austrian travellers, Dr. Hecker, and Herr von Csillagh. The party will first go to Tripolis, and direct their principal efforts to the investigation of the Shari River, and of the sources of the Binue and Congo Rivers.

CAPT. TYSON, having arrived at St. John's, Newfoundland, has sent a telegram to Washington stating that his voyage has been quite successful, and every part of the task imposed upon him has been accomplished. Capt. Tyson learns with deep regret that all has been rendered useless by the postponement of the definitive expedition.

ON reference to a map of China lately published by Mr. Stanford for the China Inland Mission, it will be seen that the missionaries of that body have for some years past been emulating their Roman Catholic brethren in the energy with which they have pushed their way into various parts of the empire. One of the most remarkable journeys, an account of which has but lately become available, was performed principally on foot, by Mr. John McCarthy, who left Shanghai in December, 1876, and reached Bhamô on August 26, 1877, having travelled a distance, including detours, of about 3,000 miles. Mr. McCarthy, though taking a somewhat different course, made the same journey as the Grosvenor Mission, and he claims to be the first non-official traveller who has thus traversed the entire width of the empire, and crossed the Kah-chen hills to Bhamô. Wearing the Chinese dress, and having nothing strange or novel with him, he was able to move along without any difficulty through the various towns and cities, and it is certainly worthy of note that throughout the whole of his long and hazardous journey he was not once obliged to appeal to an officer for help of any kind, and in no case did any officer put an obstacle in his way. The country, as far as the great commercial mart of Chungking, in Szechuen, is now comparatively so well known, that that part of Mr. McCarthy's journey was tolerably easy, but after leaving Chungking the case is different. Circumstances induced him to make for Kweiyung-fu, the capital of Kweichow; he found that the country due south of Chungking was not at all to be compared with the eastern portion of Szechuen, large tracts of land being uncultivated, towns fewer, the people more scattered, and worse housed and clothed. It would be difficult, he says, to picture the desolation of a great part of the Kweichow province; in consequence of the many years' internal strife, whole districts having been entirely depopulated. After a fortnight's stay in Kweiyang-fu Mr. McCarthy decided to walk westward, as far, at least, as Yünnan-fu, being anxious to test the feelings of the people towards foreigners. The people everywhere continued civil, and no more difficulties were met with in Yünnan than in previous portions of the journey. On the road between Yünnan-fu and Tali-fu Mr. McCarthy remarks that "the people generally are in a deplorable condition: the women compelled to do manual labour, which in other places is confined entirely to men. Men and women—but especially the latter—suffer from the formation of goitre, some of immense size." From Tali-fu to Têng-yüeh, or Momien, Mr. McCarthy says, is really the most fertile part of the country. Yungchang-fu, between these places, has been a fine city, and even now the southern part is well built over, and a good deal of business is done there. Mr. McCarthy found that the fame of the medical work at Bhamô had spread even to Momien, and during the four days' walk to Manwyne he met many Shans and Chinese who spoke approvingly of the wonderful cures effected by the foreign teachers. Having secured the services of a chieftain he crossed the hills in two days, and arrived at Bhamô in safety. This Kah-chen chief and his followers professed the greatest friendship for the English, and treated Mr. McCarthy so well that he agreed to return with him in a fortnight, in order to continue his journeys in Yünnan. This plan, however, he was obliged to give up, as he was informed by our political agent at Bhamô that he could not be allowed to re-enter China from Burmah, that being forbidden by the Indian government!

THE Wesleyan Missionary Society have recently received some very satisfactory intelligence in regard to the attitude of the natives towards foreigners in a part of Central China where they had probably never been seen before. Writing from Kwang Chi, Hankow, under date of June 7, the Rev. Thos. Bramfit says, in describing a missionary tour, that, "as Lo Tien, Ma Tsien, and the other towns have not been visited before, the people came out in crowds to see the foreigner, and to hear his doctrine; and it is to be recorded to their credit that without exception they treated us kindly, and seem inclined to give the truth a fair hearing. It may be that the Chefoo Convention has something to do with the change in the temper of the people, as compared with that in other places when first visited; but it struck us that the change is to be accounted for chiefly by the increased intercourse between the people and foreigners."

THE French Government have sent M. Léon Cahun, well known from his researches in Eastern Europe and in Central Asia, to Cyprus, on a special mission, in order to investigate the island in an anthropological and archæological direction.

NOTES

THE death is announced, on the 13th inst., of M. Delafosse, Professor of Mineralogy in the Paris Museum of Natural History and the Faculty of Science.

WE have received a "first proof" of the list of awards made to British exhibitors, from which we cull the following items:—A Grand Prix and Diplôme d'honneur have been awarded, in Class 8, Organisation, Methods and Appliances for Superior Instruction, to South Kensington; in Class 15, Mathematics and Philosophical Instruments, gold medals have been awarded to Mr. J. H. G. Dallmeyer, Mr. Howard Grubb, Messrs. A. Léqé and Co., Messrs. Negretti and Zambra, Messrs. Ross and Co., and Sir William Thomson; in Class 16, Maps and Geographical and Cosmographical Apparatus, a gold medal has been awarded to Mr. Edward Stanford; in Class 65, Telegraphic Apparatus and Processes, a Grand Prix is awarded to Prof. A. Graham Bell, for his magneto-electric telephone, without electric current; in Class 67, Navigation and Life Saving, a gold medal to Sir William Thomson, for his compass.

THE Council of the Meteorological Society have arranged for a course of six lectures on meteorology to be given at the Institution of Civil Engineers, 25, Great George Street, Westminster, on successive Thursday evenings, commencing on the 31st instant at eight o'clock. The first lecture will be by Dr. R. J. Mann, on the "Physical Properties of the Atmosphere." The other lectures will be by J. K. Laughton, F.R.A.S., R. Strachan, F.M.S., Rev. W. Clement Ley, M.A., F.M.S., G. J. Symons, F.R.S., and R. H. Scott, F.R.S. Admission to the lectures will be by ticket only, which may be obtained free on application to the Assistant Secretary at the office of the Society, 30, Great George Street.

IN a lately-issued number of the *Proceedings* of the American Philosophical Society, Prof. Cope has given an account of the collection of fishes made by Prof. Orton at various points on the head-waters of the Amazon. Species of the genera *Belone* and

Tetrodon—characteristically marine forms—are here recorded as having been obtained in these districts 2,500 miles from the mouth of the river—thus showing how far marine animals will penetrate into, and become ultimately acclimatised in, fresh waters.

THE existence of the true heath plant in North America was for a long time considered very doubtful, and its detection in New England some years ago is a matter of much interest. The published localities hitherto are Newfoundland, Nova Scotia, and Massachusetts, but, according to the *Bulletin* of the Torrey Botanical Club, Dr. Hexamer, of Newcastle, has lately found a few plants of it near Egg Harbour, New Jersey.

PROF. MORSE, since his return to Japan, has been diligently engaged in prosecuting investigations into the natural history and archæology of the coast region. During his summer's stay at Yezzo he brought together a large material of the most interesting character, the transmission of a portion of which to American museums, it is hoped, he will be able to bring about.

THE operations of the United States Fish Commission a Gloucester, Massachusetts, were brought to a close, so far as the deep-sea research was concerned, on September 26, on which day the last trip of the United States steamer *Speedwell* was made. This vessel, under the command of Capt. L. A. Beardslee, of the navy, has been diligently occupied since the middle of July in her work, and has made trips of greater or less extent, varying from five to fifty miles, nearly every suitable day during the summer. With an efficient corps of naturalists, consisting of Prof. A. E. Verrill, Mr. Richard Rathbun, and Prof. Sanderson Smith for the marine invertebrates, Dr. W. G. Farlow for the algæ, Prof. G. Brown Goode, Dr. T. H. Bean, and Mr. Earll for the fishes, and Mr. Asaph Hall, Jun., in charge of the temperature observations, very important results have been secured, the location and extent of important fishing banks have been ascertained, and existence established, of many new and important fishes and invertebrates. A full account of these will be published in the annual report of the commission. The existence of species of shark, chimæras, and other strange fishes in the deep water off the coast, has been established by numerous specimens, while the corals, gorgonians, star-fishes, and other invertebrates brought in are of the most interesting character. A portion of the commission has also been engaged during the season in collecting numerous facts in regard to the fisheries of Gloucester, especially those relating to the cod, halibut, and mackerel, the report upon which, when published, will doubtless be considered the first reliable statement of the history of this great industry.

IT is desired to enlist the co-operation of botanists in general, and more especially of bryologists, in a scheme set on foot by the Botanical Locality Record Club for investigating the geographical distribution of mosses in the British Isles. The Botanical Locality Record Club was founded in 1873 for the purpose of working out the distribution of British plants, records, accompanied by specimens as vouchers, being sent in by the members and embodied by the recorder in an annual report on the plan of "topographical botany." The club, which commenced with fifty-four members, now contains nearly 100, including some of our most eminent botanists. A large amount of work has been done by the club during the five years that it has been in existence, the floras of several counties previously almost unexplored have been worked out, and a very large number of additions have been made to the flora of many others. Up to the present time the reports have dealt only with the flowering plants and vascular acrogens. In 1875, however, a suggestion was made that the club should include in its field the other orders of cryptogamia, and it is considered desirable that, if possible, this should be carried into effect. It is proposed to start with the mosses, for which order Mr. C. P. Hobkirk, F.L.S., and Mr. H. Boswell have consented to act as recorders. A list of the mosses hitherto recorded in Great Britain, entitled "The London Catalogue of British Mosses," has been drawn up by Messrs. H. Boswell and C. P. Hobkirk, as an aid to collectors, and to secure uniformity of nomenclature. A number of specimens have already been sent in by several members. At present, however, the funds in hand are not sufficient to allow of the publication of a report on mosses without seriously curtailing the report on the flowering plants, which it is not considered desirable to do, especially seeing that bryologists constitute but a comparatively small proportion of the members of the club. If more botanists interested in mosses (say thirty) could be induced to join the club, the additional subscriptions (5*s*. each per annum) would suffice for the publication of a report on mosses. Botanists wishing to join the club are requested to send their names either to Dr. H. F. Parsons, Goole, or C. P. Hobkirk, Huddersfield.

WE are glad to see that the Metropolitan Board of Works have decided to give the electric light a fair trial by making a large and continued experiment along the Victoria Embankment and perhaps the recently freed Waterloo Bridge. The Commission of Sewers have resolved to try similar experiments on the Holborn Viaduct and in the open space in front of the Royal Exchange and Mansion House. We trust proper discrimination will be exercised in making arrangements, and if the interests of the public are alone considered, we can hardly doubt what will be the result.

Engineering has been publishing an interesting series of articles on physical science at the Paris Exhibition. In an article in the last number on the Jablochkoff system of electric lighting, some figures are given as to the total cost of the light from sixteen Jablochkoff candles, which shows it to amount to 8*s*. 6½*d*. per hour. The light of the sixteen candles is estimated by the Jablochkoff Company as equal to that of 1,600 gas-burners, each consuming 3¾ cubic feet per hour, or about 6,000 cubic feet altogether. The price of gas in Paris being 6*s*. 10*d*. per thousand cubic feet to the public and 3*s*. 5*d*. to the Administration of the Ville de Paris, it follows that the cost of illuminating by gas, equal in power to that produced by the Jablochkoff system for 8*s*. 6½*d*., would be 2*l*. 1*s*. to the public and 20*s*. 6*d*. to the Ville de Paris, while in London, taking gas at 3*s*. per thousand, its hourly cost would be 18*s*.

CARRIER pigeons, it would seem, are being turned to useful account in a new direction in Germany, for Consul Ward writes to the Foreign Office that the successful results attained by the establishment of communication between the two Eider light-ships and the port of Tönning, in Schleswig, by these means has led to the organisation of a similar arrangement between the light-vessel stationed off the Island of Borkum, at the mouth of the Ems and the island itself, whence any news brought by the pigeons can at once be forwarded by telegraph to the main-land.

SERGEANT JENNINGS, of the Signal Corps of the United States, has established a temporary station in the American section of the International Exhibition, and is practising weather-warning according to the rules of the service, as far as it is possible with his limited knowledge of the peculiarities of the Parisian climate and atmospheric conditions. This has attracted the attention of the public and scientific authorities.

MR. A. CRAIG-CHRISTIE, of Edinburgh, writes to us to say that it occurred to him some little time ago that our common grass, *Molinia cærulea*, might form a good material for paper-making, on account of its tenacity of fibre and the comparatively small quantity of silica in its composition—two characters which dis-

tinguish it from all our native grasses. He sent a small quantity of the grass to Mr. Thomas Routledge, of Sunderland, who, after experiment, concludes that, taken as dried and put up carefully in bundles, free from weeds and dirt, its value would be equal to esparto at 5*l.* per ton dry. "I, however," Mr. Routledge states, "must refrain from reporting *positively* as to its value for paper-making from the result of so small an experiment. I should require at least one ton (more would be better) to test it practically and make paper from it. . . It may be worth more than the value I mention, but only a practical working trial into paper can properly test this point." Mr. Christie writes in the hope that some of our landed proprietors may be sufficiently interested in the matter to send Mr. Routledge a quantity of the grass, so as to repeat his experiment on the large scale. The grass grows in the open parts of woods and on moorlands all over Scotland, and could be cultivated where nothing else of any value will grow. As the plant lasts for several years, the only expense after the first outlay would be that of gathering in the crop.

A DESPATCH from Poughkeepsie, dated October 4, gives the particulars of a severe earthquake shock along both sides of the Hudson from Marlborough to Peekskill, a distance of twenty-five miles. The shock was first felt at 2.30 o'clock A.M. at West Point. The shock seemed to come from the north and to pass south. For several seconds the earth seemed to rock, and houses were shaken and windows rattled. The rumbling and shock together lasted half a minute.

IN reference to the article in vol. xviii. p. 620, on the balloon experiments at Woolwich, Mr. Percy Smith writes to remind us of the fact that the first aerial voyage made in England took place on September 14, 1784, when Lunardi ascended from London in a balloon thirty-three feet in diameter, and filled with hydrogen.

M. AMÉDÉE GUILLEMIN, the well-known author of "Le Ciel" and other works on popular astronomy, has been selected by the Liberal-Republican Committee to stand as a candidate in the next elections for the French Senate, for the Department of Saone et Loire. It is stated that a number of scientific men will contend for other vacant seats.

A TELEGRAM from Sydney states that it has now been definitively decided to hold the International Exhibition in August, 1879, as gazetted last February. The Exhibition is being organised under the auspices of the Agricultural Society of New South Wales.

IN connection with the Bristol Museum and Library we have received a syllabus of a course of ten lectures, on literary and scientific subjects, to be delivered in the lecture theatre of the Museum during the winter. The lectures are mostly scientific, and the lecturers men of established eminence in their own departments.

AUSTRIA, Spain, Egypt, China, Morocco, Portugal, Russia, and England, with all her colonies, have presented the French government with all the objects which have been exhibited by them in the ethnographical and pedagogical departments of the exhibition. These invaluable collections will be exhibited in the Ethnographical and Pedagogical Museum, which the French government intends to establish, according to the announcement made by M. Bardoux in one of his last speeches.

THE *Journal Officiel* of the French republic published, on October 19, a decree of the President, appointing a general commission to investigate the means of making the best use of running waters all over France. A systematic inspection will take place. The commission has been divided into the following sections:—1. Irrigation; president, M. Andral. 2. Supply of cities; president, M. Magnin. 3. Creation of reservoirs; president, M. Cocheris. Any person wishing to suggest improvements or useful works is requested to write to the president of the section which his communication concerns. The letters are to be directed to the Ministry of Public Works.

THE number of aeronautical ascents in France is increasing in a most remarkable manner, owing to the splendid working of the Giffard captive balloon. Every Thursday and Sunday two free balloons, inflated with pure hydrogen, have been sent up from the Cour des Tuileries during several weeks. The number is to be enlarged progressively, so that three, four, and at last five mounted balloons will be sent up.

TWO volumes of the *Memoirs* of the Geneva Society of Physics and Natural History have just appeared. The first, forming the second part of vol. xxv. of these *Memoirs*, is occupied entirely by the sixth fascicule of the "Mélanges Orthoptérologiques" of Henri de Saussure, and contains the monograph on the Gryllidæ. The second volume, forming the first part of vol. xxvi. of the *Memoirs*, contains (1) a paper by M. J. E. Duby on new or imperfectly known exotic mosses; (2) a stratigraphical study of the south-west part of the Crimea, by M. Ernest Favre; (3) researches on fecundation among various animals, by M. Hermann Fol.

A FINE elephant tusk was found in the month of August last in a locality near Geneva on a hill to the south-west of the confluence of the Arve and the Rhone. It was taken from a gallery in a very compact sand along with beds of hard and tenacious gravels formed of pebbles bound together by calcareous cement. The part of the tusk which has been extracted is about eighty centimetres long; it is the anterior portion, but the fragments left behind lead to the presumption that its total length exceeded 1·50 m. The bed in which it was found belongs to the old alluvium, several metres below the glacial earth. Prof. Alph. Favre assigns it to the *Elephas antiquus*, of which *débris* were met with in 1786 by H. B. de Saussure in two places in the southern part of the valley of Geneva Lake. A portion of the parenchymatous matter contained in the interior of the tusk has been analysed by Prof. Brun, of the University of Geneva, who, having dissolved it in hydrochloric acid, obtained a residuum of organic particles—charcoal, grains of fecula, spores of algæ and of mushrooms, four species of diatoms still living in the waters of the country, and lastly a polycistina, a silicious form not well determined, and discovered previously in the mud of the Lake of Geneva. From the presence of these Prof. Brun concludes that the elephant's tusk must have been a long time in fluviatile waters.

A THIRD mathematical tract (Invariants) for American students is now being written by Dr. W. J. Wright, recently Professor of Mathematics at Wilson College, Pa. The previous tracts, which we have noticed in these columns, bore the titles of Determinants, Trilinear Co-ordinates.

ON August 29, 1879, a century will have passed since Johann Jakob von Berzelius, the celebrated chemist, was born at Westerlösa, in Sweden. The Swedish papers draw attention to this fact, and request that preparations for a dignified celebration of that day should be made in good time.

WE have received three parts (containing the concluding chapters) of the second edition of Herr F. von Hauer's work, "Die Geologie und ihre Anwendung auf die Kenntniss der Bodenbeschaffenheit der oesterr. ungar. Monarchie" (Vienna, Hölder); also a German work, by Prof. F. Lorber, "On the Exactness of Measurements of Length."

THE investigations which have been carried on for more than ten years at the Hague, in order to find out the house which Spinoza inhabited from the year 1652 until the day of his death, on February 21, 1678, have at last been crowned with success.

It is now proved that the great philosopher occupied an attic in the house, No. 28, Paveljoens-gracht in Doublet Straat, opposite to the Holy Ghost House (hoffje). The house belonged to a Heer van der Spyk. Shortly a marble tablet with a fitting inscription will be placed over the entrance.

THE German Geological Society met at Göttingen in the last week of September. The first lecture was delivered by Prof. Credner, of Leipzig, who spoke on the granite of Geyer. Then Prof. Klein, of Göttingen, spoke on a collection of thin sections of minerals forming rocks.—Herr Levin presented a petrified starfish (*Asteria cilicia*) found by him in the upper Muschelkalk of the Hainberg. This specimen is particularly interesting, being the first starfish which has ever been found in the North German limestone.—A communication was read from Prof. Martin, of Leyden, on the tertiary fauna of Java.—Dr. Hornstein (Cassel) reported on a new treatise on Eozoon by Prof. Möbius (Kiel), which will be published in Parts 5 and 6 of the "Palæontographica." Prof. Möbius arrives at the conclusion, from long-continued investigations of numerous specimens of Eozoon, that the latter is of inorganic nature.—Then followed some minor communications from Herr von Groddeck, Prof. Streng, and Prof. Weiss (Berlin), the latter pointing to a recent discovery of coal in the so-called "Eherne Kammer," some few miles to the south of Eisenach. The other speakers at the meeting were Prof. von Seebach (Göttingen), Herren Grotrian (Brunswick), Römer (Breslau), Schmid (Jena), and Prof. vom Rath (Bonn). The Society will meet at Baden Baden in 1879.

ACCORDING to a communication made at the Berlin meeting of ornithologists by Dr. Brehm, the Crown Prince Rudolf of Austria is about to publish a work on Eagles, in conjunction with Drs. Brehm and von Homeyer.

WE have on our table the following works:—"Commercial Products of the Sea," P. L. Simmonds (Griffith and Farran); "Talks about Plants," Mrs. Lankester (Griffith and Farran); "Notes on a Tour in America," H. Hussey Vivian (E. Stanford); "Philosophical Fragments," Dr. Morell (Longmans); "Geological Survey of Canada: Report of Progress for 1876 and 1877," "The Germ Theories of Infectious Diseases," J. Drysdale, M.D. (Baillière); "Sedimentary Formation of New South Wales," Rev. W. B. Clarke (Trübner); "Annual Report of the Department of Mines of New South Wales for 1877" (Trübner); "Australian Orchids," Parts 3 and 4, R. D. Fitzgerald (Trübner); "Geology of Ireland," G. H. Kinahan (Kegan Paul, and Co.); "Animal Chemistry," C. H. Kingzett (Longmans); "Manuel du Voyageur," D. Kaltbrunner (Würster and Co., Zurich); "Report on the Geological Survey of the United States," Dr. Hayden.

THE additions to the Zoological Society's Gardens during the past week include a Squirrel Monkey (*Saimaris sciurea*), from Guiana, presented by Mr. Edward Calthrop; an Emu (*Dromæus novæ-hollandiæ*), from Australia, presented by Mr. C. Hampden Wigram; two Radiated Tortoises (*Testudo radiata*), from Madagascar, presented by the Rev. G. H. R. Fisk, C.M.Z.S.; a Water Rail (*Rallus aquaticus*), British Isles, presented by Capt. F. H. Salvin; a Michie's Tufted Deer (*Elaphodus cephalophus*), from China; a Naked-throated Bell-bird (*Chasmorhynchus nudicollis*); three Blue-bearded Jays (*Cyanocorax cyanopogon*); a Dark-winged Buzzard (*Leucopternis scotopterus*), from Bahia; a Saturnine Mocking Bird (*Mimus saturninus*); two Lined Finches (*Spermophila lineola*); two Gutteral Finches (*Spermophila gutteralis*), from Pernambuco; a Pileated Song Sparrow (*Zonotrichia pileata*), from Rio de Janeiro; a Palm Tanager (*Tanagra palmarum*), from Monte Video, deposited; a Patas Monkey (*Cercopithecus ruber*), from West Africa; two Ruddy Sheldrakes (*Tadorna rutila*), European, purchased.

ON A NEW METHOD OF STUDYING THE OPTICAL CHARACTERS OF MINERALS[1]

AS is well known, the optical characters of minerals furnish us with a most valuable means for identifying the various species. The practical application of these phenomena has, however, been much restricted by the difficulty of obtaining crystals sufficiently large and transparent to be cut into appropriate sections, so that the properties of some of the commonest minerals were very imperfectly known. By the methods hitherto employed it was almost impossible to study the black or imperfectly transparent minerals constituting the chief part of rock masses, and in fact little could be learned unless the specimens were so large and perfect that the individual species could be identified by other means. What we want is a method which will enable us to ascertain the approximate value of the principal optical constants, when we have at our disposal only detached, small, and imperfect crystals in their natural state, or those scattered about in thin sections of rocks, cut into plates which are inclined at every varying angle to the optic axes.

The method now to be described satisfies these requirements sufficiently well. Time would not permit me to give a full description of the apparatus, the manner of using it, and the conclusions to be drawn from the observed data. I must therefore avoid all unnecessary detail, and confine myself to such an outline as will serve to indicate the general character of the method. I may here say that I have received most valuable assistance from Prof. Stokes in the mathematical part of the subject.

When, many years ago, I first commenced to apply the microscope to the study of minerals, I was told by a well-known professor of mineralogy that it would never be possible to learn much by the use of that instrument. If we merely magnify a portion of a pure transparent crystal, we do, indeed learn little or nothing; but if, instead of viewing the crystal itself, we look through it with a suitable magnifying power at some appropriate object, we can learn more facts of interest and importance than by any other single method whatever. The property possessed by the object-glass of collecting divergent rays to form an image gives rise to an entirely new class of phenomena, and converts the microscope into a most valuable apparatus for optical research. The object examined through the crystals is the image of a small circular hole, or of rectangular lines ruled on a piece of glass, formed at the focal point of a well-corrected achromatic condenser fixed below the stage, and so arranged that the image is placed either just below or just above the lower surface of the crystal. The divergent rays passing through it to the object-glass are bent so that the focal length is, as it were, increased by an amount depending on the thickness of the crystal and its refractive power. In order to see the lines in focus, it is therefore necessary to move back the body of the microscope. If we know the thickness (T) and the amount of the displacement of the focal length (d), we can calculate the value of the index of refraction (μ) from the equation

$$\mu = \frac{T}{T - d}.$$

These values are measured by means of a scale and vernier attached to the body of the microscope; and, with care, there ought to be no error greater than $\frac{1}{2000}$th of an inch. The thickness of the specimen (T) is determined by measuring the difference in the focal points for particles of dust on the surface of the supporting glass and on the upper surface of the mineral. In a similar manner the value of d is determined by the difference in the focal length for the lines of the grating seen through the supporting glass with or without the specimen under examination. From the value of the index thus determined a small amount must be deducted, depending upon the aperture and correction of the object-glass, and, when great accuracy is desired, several precautions must be taken to avoid a number of possible small errors, which it would be tedious to explain in detail.

In the equation, $\mu = \frac{T}{T - d}$, it is assumed that the substance possesses no double refraction, as in the case of glass or crystals belonging to the regular system. When viewed through such a substance, only one simple and undistorted image of the circular hole can be seen, and both sets of lines are in focus at the same

[1] Address by the Chairman, H. C. Sorby, F.R.S., Pres. G.S., &c., at the meeting of the Yorkshire Geological and Polytechnic Society, held in Selby on March 13.

adjustment, no matter what may be their azimuth to the axes of the crystal. We obtain by measurements and calculation one single index of refraction, but this may vary so much in different minerals as to clearly point out what they are. Thus, for example, it varies from 1·43 in fluor to 2·34 in blende. If, however, the crystal possesses strong double refraction, the phenomena are far more complex, and vary according to the direction in which the section is cut, its azimuth to the lines of the grating, and also according as it has one or two optic axes.

If we look through a parallel plate of a uniaxial crystal with powerful double refraction, like calcite, cut perpendicular to the principal axis, we see two undistorted images of the circular hole, directly superimposed, one over the other, but separated vertically by a wide interval. This doubling of the image is due to the collection by the object-glass of divergent light, since, for strictly parallel rays passing in the same general direction, there is no double refraction whatever. Both systems of perpendicular lines are seen in focus at the same time in each of the images, one of which is due to the ordinary, and the other to the extraordinary, ray. By observing these focal points we obtain two indices of refraction, one being the true index of the ordinary ray (μ), and the other not that of the extraordinary ray (μ'), but a very low apparent index, equal to $\frac{\mu'}{\mu}$.

When the section is cut in other directions the images differ very much from one another. That due to the ordinary ray has invariably the same properties. The circular hole is not distorted, and both systems of line are in focus at the same time, so that we may call that image *unifocal*. The other image, due to the extraordinary ray, instead of thus maintaining a constant character, changes very greatly, the maximum of change being when the section is cut parallel to the principal axis of the crystal. There is no focal point whatever at which the circular hole is seen of its true size and shape, and the entire circumference is never all in focus at once. There are two special foci, widely separated, at which the circle is, as it were, drawn out into a long band, at one focus parallel, and at the other perpendicular to the axis. If the section be strictly parallel to the axis the focal point of the ordinary image is nearly half-way between these two foci of the extraordinary ray, and coincides in horizontal position with the point at which the two elongated bands intersect. There is thus no lateral displacement of the images. If, however, the section be not parallel to the axis they are displaced laterally, this character being a very delicate test of the accuracy with which the section has been made. In fact, in all cases, if the two opposite surfaces are parallel, the character and position of the images at once indicate the exact relation between the optic axes and the planes of the plate, whether they be natural or artificial.

On viewing the rectangular grating through a section cut more or less nearly parallel to the principal axis, no lines whatever can be seen by means of the extraordinary ray, unless one system is nearly parallel to the axis. At one focal point one system of lines is seen, and at the other focal point the other system, so that the image due to the extraordinary ray may be said to be *bifocal*. On rotating the grating, the lines are seen to become broader, then obscure, and finally invisible. Unlike the image due to the ordinary ray, the bifocal image has thus a special focal axis, and the lines can never be seen in sharp focus if they are not either parallel or perpendicular to this axis.

On the whole, then, we have three focal points, one for the ordinary, and two for the extraordinary ray; and by observing these we obtain three different indices of refraction, one being that of the ordinary ray μ; and, provided that the section is closely parallel to the axis, the index derived from the lines parallel to the axis in the extraordinary image is the true index (μ) of the extraordinary ray, whilst the third index is of the very abnormally high apparent value $\frac{\mu^2}{\mu'}$.

The characteristic peculiarity of crystals like aragonite, which have two optic axes, is that, when the section is so cut that the images are directly superimposed without lateral displacement, they give two bifocal images, and four apparent indices. When cut in particular directions one of these images may become unifocal, but then there is a more or less considerable lateral displacement of the two images. When the section is cut perpendicular to the line bisecting the acute angle between the optic axes, so as to give two very bifocal images, the images of the circular hole are crosses at two different foci, and not, as in the case of calcite, two circles. Biaxial crystals have three true indices of refraction (μ, μ', μ''), and, if the section be accurately cut in the plane of any two of the axes of elasticity, so that there is no lateral displacement of the images, the four apparent indices observed from the lines of the gratings are as follows:—

	Polarised in one plane.	Polarised in the opposite plane.
From lines perpendicular to the plane of polarisation	μ	μ'
From lines parallel to the plane of polarisation	$\frac{\mu''^2}{\mu}$	$\frac{\mu''^2}{\mu'}$

Calling these observed indices a, b, c, and d respectively, we thus have $\mu'' = \sqrt{a\,c}$ or $\sqrt{b\,d}$. It follows from this that we can determine the value of all three indices by very simple observations, made by employing a single section cut in the plane of any two of the three axes of elasticity. Absence of lateral displacement in the images at once shows us that the specimen in its natural state, or as artificially cut, is sufficiently parallel to one of these planes to be suitable for the determination of the indices; but even if it is not such as to give all three indices absolutely true, one at least may be correct, and the others may be determined approximately. In any case the character and position of the images at once shows in what direction the section is cut, or the relation which any parallel planes of a natural crystal bear to the optic axes, though the phenomena are more complex than in the case of uniaxial minerals.

It would occupy far more time than can be allowed on the present occasion to describe in detail the curious and anomalous appearance due to dichroism or to the laminar structure of particular minerals which gives rise to complex internal reflections. My chief aim has been to call attention to the very valuable facts which may be learned by viewing a circular hole or rectangular grating with a microscope through a parallel plate of any crystalline mineral. The data thus obtained are so remarkably characteristic that they alone would amply suffice to identify a large proportion of natural minerals. In many cases all the necessary observations can easily be made with small crystals in their natural state, which alone is of course a very great gain for practical mineralogy. The chief value of the method is, however, that it enables us to identify portions of minerals of microscopic size in sections of rocks as thin, or even thinner than $\frac{1}{100}$th of an inch with an amount of certainty which leaves little to be desired.

When examining specimens of such a size that their thickness must be measured by means of the scale attached to the body of the microscope, I find that an object-glass of about $\frac{2}{3}$ inch focal length, combined with a somewhat highly magnifying eye-piece, gives the best results. When, however, we come to study the minerals in moderately thin sections of rocks, it is impossible to measure the thickness and the displacement of the focus sufficiently accurately by means of the scale and vernier. The fine adjustment screw of the microscope may then be employed along with a $\frac{2}{5}$ or $\frac{1}{5}$ object-glass, and, if properly constructed and used, the requisite measurements may be made to within $\frac{1}{20000}$th of an inch. We may thus approximately determine the indices in sections only $\frac{1}{1000}$ of an inch in thickness. It is, however, necessary to adopt a system which reduces the number of separate measurements and to a great extent eliminates several sources of error. Instead of attempting to measure the *absolute* thickness of any particular crystal, and the actual displacement of the focal length due to it, the *apparent* thickness of the mineral, *as seen through itself* (t), is measured by means of the rotation of the graduated circular head of the fine adjustment by focussing, first to the top and then to the bottom, of some appropriate specimen. In each particular substance this apparent thickness is equal to the true thickness divided by the index of refraction. The thin glass cover is made somewhat larger than the section, so as to project beyond it, and inclose a layer of the hard and brittle balsam used to fasten down the piece of rock. Selecting for observation a specimen as near as possible to this balsam, so as to avoid any error due to unequal thickness, the difference (d') in the displacement of the focal length due to the mineral and the balsam is ascertained by focussing through each the lines of the grating. This value is positive or negative, according as the index

of the mineral is greater or less than that of the balsam. It then follows that $t \pm d'$ is the thickness, as seen through itself, of the amount of balsam of the same real thickness as that of the mineral: the effects of the balsam below and above it, and of the covering-glass, being thus entirely eliminated. If, then, the index of the balsam be m, we can easily calculate that of the mineral (μ) from the following equation:—

$$\mu = m \frac{t \pm d'}{t}.$$

In the case of the hard and brittle balsam used to fasten down the specimen, the value of m is about 1·54; but if there be any doubt about the true index, it can be ascertained by special measurements.

In a similar manner we may determine the index of some unknown mineral by comparing it directly with some other mineral lying near to it, the true index of which is either well known or has been previously ascertained from special measurements. For this purpose quartz is often very suitable, since its index varies very little. One great advantage of this method is that specimens may be observed far away from the edge of the section, provided of course that the minerals compared are so close together as to prevent any error due to unequal thickness in different parts.

It must be borne in mind that, when any mineral has a very powerful double refraction, its apparent thickness, as seen through itself, varies according to the particular ray used for illumination and the direction of the objects chosen to determine the focal distances of the lower surface. There is, however, generally no difficulty in measuring with sufficient accuracy the mean apparent thickness, or that corresponding to some one image, and in calculating out the results accordingly.

In connection with this subject it may be well to call attention to a somewhat interesting fact. If we have, side by side, two substances of different refractive power, but of the same *absolute* thickness, their apparent thicknesses, *as seen through themselves*, vary directly as the velocity with which light moves in them. Indeed, strictly speaking, the determination of minerals in the manner now described depends entirely on an indirect measurement of the velocity with which light is propagated through them in different directions.

In order to illustrate the practical applications of this method, I will describe the results obtained in the case of a section of dolerite from near Glasgow, which, on an average, is about $\frac{1}{400}$th of an inch thick.

I found that the index of a colourless transparent mineral, filling up cavities between the original minerals, was about 1·48 or 1·49. This exactly corresponds with that of analcime, with which its other optical characters agree.

Another colourless mineral, also filling cavities, was found to have the indices and other characters of calcite.

A third colourless mineral, evidently an original constituent, was seen to have a comparatively feeble double refraction, and its index was found to be 1·61. Its general appearance was like that of some felspar, but this index clearly proves that it cannot be any species which contains a considerable amount of alkali, which would greatly reduce the refractive power. The index of labradorite was not previously known, but I find that it is 1·61, and therefore there can be little doubt that the mineral in the section is that species.

The section also contains a number of transparent reddish-brown crystals, their index of refraction being about 1·79. This and their other optical characters closely agree with those of the dark augite in the lava of Vesuvius.

In now concluding this short address I cannot but feel that I have been obliged to omit all allusion to many points of considerable practical importance. I have not attempted to describe the subject in such a manner as would enable any one to at once practically apply the method in all sorts of cases. I gave a somewhat full account of one branch of the subject in my address at the meeting of the Mineralogical Society at Plymouth, and entered into the more purely microscopical aspect of the question in my late address at the anniversary meeting of the Royal Microscopical Society. I propose to communicate a detailed paper to the Royal Society as soon as a correct explanation can be discovered of certain small but remarkable discrepancies between mathematical theory and observation. My chief object now is simply to point out what valuable facts may be learned respecting the nature of any mineral by looking through it with a microscope at a circular hole or rectangular grating. This is a totally different thing to magnifying the mineral itself, or to looking through the mineral at any distant object without a microscope. The success of the method depends entirely upon the optical conditions characteristic of a compound microscope. I have lately greatly improved the apparatus hitherto employed, but the examples already given will, I trust, serve to prove that, even with the less perfect appliances, it was possible to identify in a very satisfactory manner, many of the minerals met with in their microscopical sections of rocks, and thus to determine their constitution with far more certainty than heretofore.

RECENT OBSERVATIONS UPON THE PLACENTATION OF THE SLOTHS

M. JOLY has recently brought before the Academy of Sciences of Paris the results of a careful examination of the structure of the placenta of the Aï, or Three-toed Sloth (*Bradypus tridactylus*, Linn.), and proposes important changes in classification, after comparison of this structure with that of certain allied mammals.[1]

It is now six years since we contributed to NATURE a notice of the observations of M. Alphonse Milne-Edwards upon the fœtal envelopes of another member of the Edentata, the "Tamandua" Ant-eater, published by him in the *Annales des Sciences Naturelles*. This Edentate is there stated to have a "placenta discoïdal envahissant."

The sloths are literally, as Buffon described them, ruminant animals, in that they have four stomachs, but they are, at the same time, wanting in all the other characters which pertain to Ruminants proper. Linnæus, on the contrary, classed them, at first among the Primates, but afterwards among the Bruta—the "Edéntés" of Cuvier—and his example was followed by De Blainville. Cuvier placed the "Tardigrades" (*Bradypus*) at the head of the Edentata, although they possess well-developed canine and molar teeth.

It will be seen, then, that as regards the position of these animals the embarrassment of the taxonomist has been extreme, as the genus *Bradypus* has been bandied about from the Ruminants to the Primates, and from these latter to the Edentata. Latterly, however, great importance—and with good reason—has been attributed to the structure of the placenta, as affording characters distinctive of the various groups of mammals, and as giving valuable indications of their zoological affinities. The classification of the placenta by Carl Vogt, though scarce a quarter of a century old, into zonary, diffuse, and discoidal, is nowadays acknowledged to be incomplete, nay, even faulty in some of its applications; for we know now, thanks to the work of Alphonse Milne-Edwards, that if the majority of Ruminants have a multicotyledonary placenta, the camel, the chevrotain, and the *Tragulus* have, on the other hand, one of the diffuse variety. It is the same with the digitigrade Pachyderms (wild boar, &c.), while the plantigrade ones (*Proboscidea, Hyracoidea*) differ from the first in having a zonary placenta like that of the Carnivora and Amphibia (seals, &c.). In fine, although stated to be so, this organ is neither diffuse nor subdivided among any of the Edentata studied from the point of view of their placentation. Nay, more; among these animals the placenta offers, according to genera, and even according to species, differences so well marked that it is necessary, following the apposite remark of M. Alphonse Milne-Edwards, to give up seeing between the different types of Edentata affinities as narrow as those which are supposed, even now generally, to exist among them. Carus has represented the placenta of the Aï, or three-toed sloth, as being multi-lobed, but he does not give any precise information as to the number of these lobes, their structure, the extent which they occupy relatively to the membranes of the ovum, and their connection with the uterine mucous membrane [decidua ?], &c.

The placenta of the Aï examined by M. Joly presented itself under the form of a veritable membranous pouch constituted by the amnion and the chorion, and garnished, on almost all its external surface, with a large number (more than a hundred) of lobes or cotyledons of more or less irregular shape and of very variable size, from one millimetre to one or two centimetres. Viewed from the external face of the placenta, these cotyledons appear, some rounded and flat, like Nummulites, others of the form and size of seeds of millet. Others, lastly, much larger, grouped in numbers together, recall by their aspect the multi-

[1] *Comptes Rendus*, August 12, 1878.

lobed kidneys of birds and of certain Ophidian reptiles. Cavities, more or less roomy, in which are doubtless inserted the vessels of the hypertrophied mucous membrane, are also visible on the outer surface of the fœtal placenta. But it is specially upon the internal aspect that the lobules form numerous folds exactly limited, of a thickness frequently considerable (more than one centimetre), strongly adherent to the chorion by a pretty long base, free for the most part for the rest of their extent. We can understand, then, up to a certain point, that Carus should have been able to compare this placenta with that of the ruminants, from which it nevertheless differs much, since its cotyledons are made up of full lobes, generally antiguous, and not of isolated capsules, and distant one from the other like those of the fœtal placenta in the cow, or the maternal one in the sheep.

But we are as yet more disposed to assimilate the placenta of Aï to that of the Lemuroids, notably that of the *Propithecus* of Madagascar, which has been described by M. Alphonse Milne-Edwards under the name of *placenta en cloche* or *placenta envahissant*. In Aï, as in *Propithecus*, the chorion is covered almost entirely with thick and crowded villosities, constituting a kind of vascular cushion resulting from the confluence of a multitude of irregular cotyledons. But the Aï approaches *Propithecus* not only in the structure of the placenta but also in its habits, for both are arboreal, and have a diet exclusively vegetable. Besides this the uterus of the Aï is pyriform, like that of the human female and the female of most apes, a peculiarity which, with the possession of pectoral mammœ, approximates *Bradypus* to *Propithecus*. Linnæus and De Blainville seem then to have been guided by a "kind of divinatory intuition," as it were, when they ranked the sloths of Brazil in the order of Primates, only that they ought not to be classed among the apes proper, but by the side of the *Propithecus* of Madagascar and the slow Loris of the East Indies, of which they are the analogues, or American representatives.

M. Joly finally concludes thus: By its bursiform placenta, as well as by many other peculiarities of organisation, the Aï is a Lemuroid, and not an Edentate.

Not the slightest allusion is made by M. Joly to the well-known publications of Prof. Turner upon the comparative anatomy of the placenta, and especially to a paper read before the Royal Society in May, 1873, upon the fœtal structures of that variety of two-toed sloth called by Prof. Peters *Cholœpus Hoffmanni*.

J. C. GALTON

UNIVERSITY AND EDUCATIONAL INTELLIGENCE

THE Master and Fellows of Gonville and Caius College, Cambridge, have considerably enlarged the chemical laboratory of the College, and have added a small but very serviceable lecture-room, with apparatus-room adjoining. They have likewise provided a private laboratory for the Prælector. The main laboratory now accommodates fifteen students working at one time.

UNIVERSITY COLLEGE, BRISTOL.—The third session of this young institution opened on October 8. The competition for the entrance scholarships was closer than any preceding year, and the general standard of attainments higher. The engineering department of the College is now fairly started, and is almost, if not quite, unique in character, the principal engineering firms in the district having agreed to an arrangement, whereby they receive into their works the engineering students of the College for the six summer months, the six winter months being devoted to the theoretical training of the College. The number of male day students of the College has largely increased; the entries in classical and modern literature, in chemistry, mathematics, and physics, exhibiting a satisfactory increase on those of the preceding year. The attendance at the evening classes is also very large. The scientific side of the College course has been strengthened by the appointment of Mr. W. J. Sollas, M.A., F.G.S., as lecturer on geology. A course of lectures on analytical chemistry is being given by Prof. E. A. Letts, who also resumes his industrial lectures on Dyeing and Scouring at Stroud.—Mr. J. Clapham also continues his course of instruction on Textile Fabrics. A course of lectures on the Technical Applications of Electricity, by Prof. S. P. Thompson, is also announced. The morning lectures on Political Economy are this year delivered by Mrs. Paley Marshall.—Mr. L. A. Goodeve, B.A., has been appointed lecturer on Law.

SCIENTIFIC SERIALS

The American Journal of Science and Arts, September.—In an opening paper on the origin of comets Prof. Newton compares the hypotheses of Kant and Laplace, the former of which represents that these bodies are formed from the matter of the condensing solar nebula; the latter, that they have no relation with this, but were made from matter scattered through stellar space. He shows that the curve of actual distribution of the inclinations of cometic orbits to the ecliptic, agrees well with that required by the hypothesis of Laplace, if we first make reasonable allowance for known perturbations, and for the comets of short periods, but that it is not thus made to agree with Kant's hypothesis.—Prof. Gray explains the distribution of tree species in North America, and traces similar species dispersed over widely-separated continents to a polar centre, where they once flourished in a temperate climate. Among other facts he mentions that while the Atlantic American Forest has almost three times as many genera and four times as many species of non-coniferous trees as the Pacific Forest, it has slightly fewer genera, and almost one-half fewer species of coniferous trees.—Prof. Marsh describes a new pterodactyl from the Jurassic of the Rocky Mountains.—Professors Draper and Watson give their observations on the solar eclipse, and an intra-Mercurial planet respectively.—The animal of *Millepora alcicornis* is figured by Mr. Rice, who confirms the conclusions of Agassiz.—Prof. Verrill notes some additions to the marine fauna of the east coast of North America; and among chemical notes is one on antimony tannate, by the Misses Swallow and Palmer.

Journal de Physique, September.—Some experiments showing the power of a vibratory motion to produce decomposition of explosive liquids and ebullition of superheated liquids are here described by M. Gernez. They consist in rubbing with a damp cloth a clean glass tube containing, *e.g.*, supersaturated seltzer water that has been kept in it for months, or a little nitrous acid below water, or methylchlorhydric ether. In the two former cases there is a projection of liquid; in the latter, a vigorous boiling occurs but soon ceases, owing to the consumption of heat by the vapour formed, reducing the temperature to near the normal boiling-point.—M. Cornu gives an account of his valuable researches on the ultra-violet solar spectrum, which have from time to time been communicated to the Paris Academy.—M. Planté describes effects got with his rheostatic machine; it gives, in general, all the effects of electric machines and induction coils, and these are not apparently much interfered with by the hygrometric state of the air.—We note, among the abstracts, one of recent proceedings of the St. Petersburg Physical Society.

Atti della R. Accademia dei Lincei (Rome) 1876-77, vol. i.—This part commences with a second instalment of Prof. Respighi's memoir on the latitude of the Roman Observatory.—On fluoride of magnesium, by A. Cossa.—On the theoretical velocity of sound and the molecular velocity of gases, by A. Rieti.—Petrographical studies, by G. Struever (two plates).—On the constitution of chloral ammonia and aldehyd-ammonia, by R. Schiff.—Electrostatic researches, by P. Volpicelli.—On the microscopic aspect of certain nervous fibres, by Franz Boll (two plates).—On some palæozoic fossils of the Maritime Alps and of the Ligurian Apennines, by B. Gastaldi (four plates).—On an objection to Melloni's theory of electrostatic influence, by P. Volpicelli.—Memoir on modular equations, by H. T. Stephen Smith.—On the dilatation, the capillarity, and the viscosity of fused sulphur, by G. Pisati.—On the titanite and the apatite of the Lama dello Spedalaccio, by G. Uzielli.—On the direction of gravity at the Barberini Station on the Monte Mario, by F. Keller.—Experimental researches on the tenacity of metals at different temperatures, by G. Pisati, C. Saporito, and S. Scichilone. The author experimented with copper, steel, brass, and aluminium.—Geological investigation of the mountain group of the Gran Paradiso, by M. Baretti (with seven carefully executed maps).—Experimental researches on electric discharges, by A. Richi (five plates). This and the previous one are amongst the most elaborate papers in the volume.—On the small oscillations of a rigid and perfectly free body, by V. Cerrutti.—On the anatomy and the physiology of the retina, by Franz Boll (one plate).—Ephemerides and statistics of the River Tiber before and after the confluence with the Aniene River, during the year 1876, by A. Bettocchi.—On some cave miriapoda of France and Spain, by F. Fanzago.—On the duration of vitality in the germinative spot, by Dr. G. Colasanti.

—Researches in theoretical crystallography, by G. Uzielli.—On the experimental determination of the electric density on the surface of conducting bodies, by E. Beltrami.

Reale Istituto Lombardo di Scienze e Lettere, Rendiconti, vol. xi. fasc. xiv.–xv.—We note the following papers in this number:—Colouring matters contained in the grape and a new means of judging of the degree of ripeness of this fruit, by S. Pollacci.—Transformation of hydroxylamine into nitrous acid, by Dr. Bertoni.—Action of solar rays on haloid compounds of silver, by Dr. Tommasi.—Reduction of chloral, by the same.—Results of vivisection of the cerebellum, the transverse peduncles, the semi-circular canals, and the nerves of taste, by Dr. Lussana.

SOCIETIES AND ACADEMIES

London

Entomological Society, October 2.—H. W. Bates, F.L.S., F.Z.S., vice-president, in the chair.—Mr. J. Lawrence Hamilton, M.R.C.S., was elected a Subscriber, and Mr. Thos. Nottidge a Member of the Society.—In reference to the statement of Mr. F. Smith at the last meeting of the Society, to the effect that the Linnean collection of insects contained in the apartments of the Linnean Society had fallen into a state of complete neglect, Mr. McLachlan read a report on the result of an examination he had since made of that collection. Mr. McLachlan considered that the collection was now in the same condition as it had been for probably a quarter of a century, and that the charge of neglect could not be sustained. Mr. Stainton fully corroborated this view, and stated that from a recent examination of the lepidopterous portion of the collection he had been unable to detect any appreciable deterioration in it since the year 1848, when he had first occasion to consult it.—Mr. Jenner Weir exhibited specimens of *Hipparchia semele* from various localities, showing a tendency to vary in colour on the under side in accordance with the nature of the soil of the district in which the specimens had been taken.—Mr. McLachlan exhibited the eggs and young larvæ of *Ascalaphus longicornis*, found by M. E. L. Ragonot, in the Forest of Lardy, apparently the northern limit of distribution of the species. Mr. McLachlan also exhibited, on behalf of Mr. Edwin Birchall, an example of *Heliothis scutosa*, captured by Mr. Campbell in the north of Co. Donegal, Ireland.—Mr. Rutherford exhibited and communicated a description of a new species of cetoniidæ, from Mount Camaroons. Mr. Rutherford also exhibited a specimen of *Ranaleosoma ruspina*, which was curiously and symmetrically destitute of scales.—Mr. Champion exhibited specimens of *Amara infima*, taken at Cobham, Surrey.—Mr. Forbes exhibited a collection of insects from Switzerland.—Mr. Wood Mason read a note on a saltatorial *Mantis*, and exhibited a specimen of the insect which had been captured on the banks of the Tagus. He also read notes on the hatching period of Mantidæ in Eastern Bengal, and on the presence of stridulating apparatus in certain *Mantidæ*. Mr. Wood Mason also stated that he had discovered a remarkable case of viviparity in an orthopterous insect, *Panesthia javanica*, a cockroach inhabiting the tropical forests of Southern Asia and Australia.

Paris

Academy of Sciences, October 14.—M. Fizeau in the chair.—The President announced the death of M. Delafosse, member in the Section of Mineralogy.—The following papers were read:—Presentation of vol. ix. of the "Observations of Pulkowa," by M. Otto Struve. This contains micrometric observations made by the author during forty years (with the same instrument and by the same method) on double and multiple stars. They continue the series of twelve years' like observations by his father at Dorpat. By these measurements M. Struve has been able to observe, *e.g.*, the epicycloidal motions of the third star in ζ Cancri, to determine approximately the orbit of 42 Comæ Ber., and clear up the controverted system of 61 Cygni. The measurements in this volume relate chiefly to double stars of the Dorpat catalogue, in the northern hemisphere, and to all systems discovered at Pulkowa. Another volume will contain extended observations.—Formulæ relating to perforation of iron armour plates, by M. Martin de Brettes.—M. Decharme presented a supplement to his memoir on vibratory forms of solid or liquid bodies; it relates to experiments with a large glass plate, with which the former results (with small plates) were confirmed.—M. Champin communicated an observation regarding transformation of apterous into winged phylloxera in the galls.—Third letter of Prof. Watson on the discovery of intra Mercurial planets. M. Mouchez considered the information here given answered his objections in great part, and left no doubt of the reality of the discovery of at least one of the two planets.—Reply to a communication by Herr Weber on thermodynamics, by M. Levy.—On a new micrometer, meant especially for meteorological researches, by M. Govi. In this the threads or fine wires are replaced by the two edges of a slit made in a very thin layer of silver, gold, platinum, or other inalterable metal, placed on the surface of a plate of glass having perfectly plane and parallel faces. The slit is produced by means of a light metallic tracer; and for larger slits the tracer is made to remove the metal in advancing parallel lines. Advantages attach to the extreme thinness of the metallic layer, its opacity, rigidity, and inalterability under considerable thermometric and hygrometric changes, the possibility of easily making slits as narrow or as wide as may be desired, and the facility of substituting different plates for each other in the same frame.—On a new metal, *philippium*, by M. Delafontaine. It is so called in honour of M. Philippe Plantamour, of Geneva, the friend and pupil of Berzelius. The author's former conclusions are confirmed; the new earth (of samarskite), which has a colour and a molecular weight intermediate between those of yttria and terbine, is not a mixture of these two bodies, but an oxide of a new metal. Supposing provisionally that philippine is a protoxide, its approximate equivalent is between 90 and 95. M. Delafontaine gives the properties of some compounds, the philippic formiate, sulphate, nitrate, &c., and describes the spectroscopic appearances gievn by concentrated solutions of philippium. These present a very broad characteristic absoption band which is absent from terbic, yttric, and erbic solutions.—Action of the juice of beet-leaves on perchloride of iron, under the influence of light, by M. Pellet. It has, in absence of chlorophyll, the power of reducing salts of iron easily, in light. This reduction may take place in the dry state, and with solutions having no longer vitality. It is due to oxidation of several organic substances contained in the leaves, such as sugars, tannin, azotised matter, &c.—M. Ronder presented a note on an arrangement for observing the stars in broad daylight, without the aid of a telescope; it consists in the use of a long tube, the lower end of which terminates in a dark chamber.

SCIENTIFIC WORTHIES

XIII.—SIR GEORGE BIDDELL AIRY

SIR GEORGE BIDDELL AIRY was born at Alnwick, Northumberland, on July 27, 1801. He was first educated at private schools in Hereford and Colchester, and passed at the age of eighteen to Cambridge, where he entered at Trinity College as sizar. Here he developed his love for mathematics and graduated as senior wrangler in the year 1823.

In the following year, being elected a Fellow of Trinity College, he was closely engaged with the introduction of a new class of studies into the University, and published his "Mathematical Tracts on the Lunar and Planetary Theories," the "Figure of the Earth," &c., and the "Undulatory Theory of Optics," a work of considerable merit, which showed at once both the ingenious mathematician and the accomplished philosopher. In the year 1825 he wrote for the Cambridge *Transactions* papers "On the Forms of the Teeth of Wheels," and "On Escapements."

In the following year he was elected Lucasian Professor of Mathematics, and applied himself with the utmost ardour to the promotion of the knowledge of experimental philosophy in the University, and a great many of his papers, published at that time and afterwards in the *Transactions* of the Cambridge Philosophical Society, bear on those subjects, and principally on the most remarkable of them, Undulatory Optics, a field of research quite new at that time. The requirements of universities were never afterwards lost sight of. He gave, for instance, in the year 1868, a course of lectures in the University of Cambridge on the subject of Magnetism, with the view of introducing that important department of physical science into the studies of the University. His books—"Theory of Errors of Observations," "On Magnetism," and various memoirs in the *Transactions* of learned societies were written principally for this purpose.

In the year 1828 he was elected Plumian Professor of Astronomy, and was charged with the directorship of the Astronomical Observatory, where he had to superintend the erection of several instruments, principally the mounting of the great Northumberland equatorial, which was constructed almost entirely under his own direction. In the same year he was elected a Fellow of the Royal Astronomical Society; and now commences an activity which is almost unsurpassed in the annals of astronomy.

Prof. Airy, after the example first given by Maskelyne, and followed by Bessel and Struve, introduced into the observatory a most efficient system for reducing the observations, and printed them annually. The greatest regularity in the routine of consecutive years was aimed at and attained, in great measure, from adherence to the rule of forming the plan of observations for each year in the greatest detail practicable before the close of the preceding year.

These practical occupations did not divert his mind from theoretical studies. In the year 1831 a most important paper was published in the Cambridge *Transactions*, "On the Inequality of Long Period in the Motions of the Earth and Venus." In the following year he wrote for the British Association a very interesting "Report on the Recent Progress of Astronomy," a little work which may be read still with great profit by every student of astronomy. Various lacunæ of our science discovered on that occasion were filled up by Prof. Airy in the next year by his papers "On the Mass of Jupiter."

When Mr. Pond, the fifth Astronomer-Royal, resigned in the year 1835, Prof. Airy was appointed his successor, by Lord Auckland, first Lord of the Admiralty, and at the same time he was elected President of the Royal Astronomical Society. During the forty-three years that have elapsed since his appointment as Astronomer-Royal, Sir George has always been most keenly intent in promoting astronomy and science in general in every way.

He has equipped the Royal Observatory at Greenwich with a series of new instruments of very exact construction, all made after his own designs, many of them invented by himself. The first of the new instruments was erected in the year 1847. It was constructed in as few separate parts as possible, and no important parts were connected by small screws, in order that the instrument might possess the greatest amount of firmness. The end to be attained by its use was to make observations out of the meridian as accurate as observations in the meridian, and its main object of observation was the moon. It must be recollected that the moon can very seldom be observed with the meridian instruments before her first quarter and after the last. The altazimuth was designed to obtain observations of her as often as she was visible in the sky and, I am sure, every astronomer will agree that the erection of this instrument was a most important innovation. Its great services were fully acknowledged many years later, when the greatest errors in Burkhardt's Tables of the Moon were shown to exist in parts of her orbit never accessible to meridian observations. The number of days on which the moon is observed by this instrument is nearly double that of the observations in the meridian.

At the end of the year 1850 the new meridian circle was erected, the object-glass of which, made by Mr. Simms, has 8 inches clear aperture and 11 feet 6 inches focal length. With this instrument there was also introduced a great change in the observing routine at Greenwich, the transits and the zenith distances of the stars being now taken by one astronomer at the same time. Nearly simultaneously the American method of observing transits was adopted.

The Troughton zenith-sector, found by Mr. Airy at the Observatory, had given much trouble, and various alterations had not improved the results obtained by it. It was therefore dismantled in the year 1848, and the "reflex-zenith-tube" erected, an instrument admirably calculated for observing the small changes in the zenith distances of γ Draconis, the Greenwich zenith-star.

When all these new instruments were well in working order, Mr. Airy directed the attention of the Board of Visitors, in the year 1855, to the fact that the extra-meridional apparatus was by no means fit for the present wants of astronomy. A large object-glass (12 French inches in diameter) was, in consequence, procured by the Astronomer-Royal from Mr. Merz, and was mounted

in the manner which was formerly adopted by Mr. Airy in the mounting of the equatorials at Cambridge and Liverpool. With the inauguration of the new equatorial in the year 1859 the change from the old state of the Observatory was complete. There was not then a single person or instrument in the Observatory that had been there in Mr. Pond's time.

A fifth new instrument was planned by Mr. Airy in the year 1869, and erected in the following year in the Royal Observatory, in order to decide the most delicate question of the dependence of the measurable amount of sidereal aberration upon the thickness of the glass or other transparent material in the telescope. The tube of a telescope (the lenses of which were ground to proper curves) was filled with water, and the telescope mounted as zenith-sector. Several years' observations of γ Draconis did not reveal a perceptible difference in the constant of aberration found in this manner from the value generally adopted.

Of the instruments invented by Sir George Airy I may mention also the double-image micrometer, a very useful apparatus, if thoroughly investigated; the eye-piece for correcting the atmospheric dispersion; the orbit-sweeper, a most ingenious contrivance to detect comets approaching perihelion passage, the time of which cannot be exactly fixed.

The observations were made, under his own responsibility, during nearly half a century, without interruption, reduced with great care, regularly printed, and—a very essential thing—very liberally distributed. They form a vast collection of the most important fundamenta of astronomy. Every year Sir George publishes a report on the work done in the Royal Observatory; these reports form a series which will be of the greatest use for the writer of the history of astronomy and science in general in the nineteenth century.

Since the year 1833 the incessant activity of Sir George Airy had been directed to an undertaking, proposed to astronomers by Bessel, in the preface of his "Tabulæ Regiomontanæ," viz., the reduction of the Greenwich lunar and planetary observations since 1750. This most arduous task was completed in the year 1848; and we may say that our present tables of the motions of the moon and the planets rest, for the greatest part, on those bulky volumes, containing these reductions.

But not only was this immense magazine of dormant facts opened by Sir George to science: he reduced also the observations of Groombridge, of Catton, and of Fallows, the first Astronomer-Royal of the Cape of Good Hope. The importance of these reductions is not limited by the usefulness of the observations themselves to the astronomer by the appearance of the "Star-Catalogue," containing Mr. Groombridge's most valuable observations. Mr. Johnson, for instance, was induced to undertake those beautiful observations of circumpolar stars, forming afterwards the Radcliffe catalogue of stars. Prof. Hansen, of Gotha, was very materially supported by the Astronomer-Royal in finishing his great work on the moon and calculating tables of her motion.

The pressure of daily work and the responsibility of keeping up the Greenwich series of solar and lunar observations absolutely uninterrupted, did not prevent the Astronomer-Royal from taking up other scientific questions of the day. In the year 1842 he made a voyage to Turin, in order to observe the total solar eclipse; the same object induced him to visit Gothenburg, in Sweden, in 1851, and to organise, in the year 1860, the famous *Himalaya* expedition to Spain.

His great interest in every branch of his favourite science is evinced by the recent introduction at Greenwich of heliographic and spectroscopic services.

In the year 1847 Sir George went to Russia for the purpose of inspecting the new Russian Central observatory. It is highly gratifying to read with what absence of prejudice the great astronomer expresses himself in regard to this observatory, the personal establishment of which and the construction of instruments is so very different from those at Greenwich.

Magnetical and meteorological observations were not made at Greenwich before the time of the present Astronomer-Royal. Sir George Airy proposed to the Government to make them at Greenwich, and since 1838 the new Magnetical and Meteorological Observatory has been in activity. He introduced for this department also the self-registering instruments constructed by Mr. Brooke.

In later years the Astronomer-Royal has been oppressed with the difficulty of making the meteorological observations practically available. With a store of records, extensive, accurate, and rich, beyond any other which exists, he does not see a probability of physical connections or physical laws sufficiently strong to induce him to enter confidently on an expensive comparison, and he expresses strongly his opinion, that the want of meteorology at the present time is principally in suggestive theory.

Only very briefly can I mention his very useful experiments on iron-built ships, for the purpose of discovering a correction for the deviation of the compass, which resulted in a system of mechanical corrections, universally adopted; his researches on the density of the earth by observations in the Harton Colliery; his extensive aid to Government in recovering the lost standard for measures; in fixing the breadth of railways; in introducing a new system for the sale of gas, &c. All these transactions have proved Sir George Airy "the thorough man of business." Indeed, the promptness of his correspondence and his kindness in answering every scientific inquiry in the most minute manner, is most remarkable and seldom to be met with in so profound a philosopher.

In recent years the Government intrusted to his care the equipment and instruction of the British Expedition for the Transit of Venus, a subject which had engaged the attention of the Astronomer-Royal during thirty years, and had induced him to write a number of most important papers on the matter. In the year 1848 he gave a series of lectures on this difficult subject at Ipswich. The whole responsibility for reducing the observations made during the transit rests likewise with him. Much of his time has, during the last few years, also been spent in promoting the lunar theory by a method of his own.

Sir George Airy has, of course, deservedly received the recognition of his country and the scientific world in general. He is medallist of the French Institute,

of the Royal Society (twice), of the Royal Astronomical Society (twice), and of the Institute of Civil Engineers. Most scientific societies are proud to have his name on their list of members; he is one of the eight Associés Étrangers de l'Académie des Sciences à Paris.

A. WINNECKE

FOREIGN ORDERS

IN several articles and letters in vol. viii. of NATURE the question of the conferment of foreign orders on British subjects, so far as it concerns men of science, was pretty thoroughly discussed, as well as the proposal made in Parliament, in 1873, to establish an order of intellectual merit. The subject has again come up in connection with the distribution of awards at the close of the Paris Exhibition, and there has been much disappointment and even bitterness of feeling expressed at the refusal of our Government to allow British subjects to accept the coveted Cross of the Legion of Honour. It is well known that many of our men of science, as well as others, possess foreign orders in abundance, and that our Government takes no notice unless consulted, when, on the ground of some antiquated regulations, it thinks it its duty to refuse permission to accept such orders. If not illegal, it is at any rate weak and childish on the part of Government to take such a course, worthy of the days of "good" Queen Bess, who wished her dogs to wear no collars but her own. In the case of the Exhibition awards it has been shown that this decision on the part of our Government falls with peculiar hardship on British exhibitors. It will very naturally be inferred by the general public that as a body they occupy an inferior position to foreign exhibitors, who are allowed to accept the great French honour, which is conspicuous by its absence from the awards in the British department. It is especially hard, we think, upon those who have served on the British jury. From some parsimonious caprice on the part of Government no allowance was made to those who served as jurors at the Paris Exhibition, and the eminent men of science who gave up their time and knowledge for the benefit of the country and the world not only go entirely unrewarded, but must have been seriously out of pocket. One case we know of—and we believe it is not the only one—where a well-known chemist, besides incurring serious expense, worked so hard as to materially affect his health, and all not even for bare thanks.

So far as we ourselves are concerned, we are not anxious to see men of science eager to obtain, or easy to be satisfied, with such honours as those which, if they are simple enough to ask, they are told they must not accept. Our own Government is niggardly enough in its recognition of the services done by the scientific worker to his country; and how can it be otherwise with a Cabinet that has scarcely a member, we believe, who knows the difference between a telescope and a telephone. Fortunately for his self-respect, the purely scientific worker, however eminent he may be as such, is rarely, if ever, embarrassed by the offer of honours from our own Government. These are reserved for the militant and civil services, where, as a rule, they are least requisite, seeing that those who obtain them are generally pretty well paid for their zeal. As for what is called the "honour" of knighthood, it has now become so common, so easily obtainable, that the mere offer of it must make one suspect that after all he must be regarded by its dispensers as a very tenth-rate man. We know of a humble grocer in a small country town in the north in which a statue erected to the late Prince Consort was unveiled by the Queen, when the decent man happened to be provost; of course he was dubbed "Sir," and his life was ever after rendered miserable by the waggish little urchins of the town, who would gravely pass their cans across the counter for "A bawbee worth o' treacle, Sir Dawvid." And C.B. is rapidly becoming little better, so that virtually in this country there is no imperial honour attainable by the purely scientific worker, however eminent, which his self-respect would permit him to accept entirely without question.

As to the creation of an order of merit for men of high eminence in science, literature, or art, we have already expressed our opinion. In the present state of things it is better to let the existing chaos alone. Who is there among those who would now have the dispensation of such an honour who is capable of selecting those really most worthy of it? Had we a Minister of Science, with a council of scientific specialists to guide him, then there would be some chance that such an honour would reach those who really deserved it; but at present it is hopeless. Indeed the devotee of scientific research would much prefer that Government, if it desires to do science honour, would do so by giving her substantial aid to pursue her work, than that it should load her servants with all the honours at her Majesty's disposal.

Still with the parsimony both of money and "honours" at home, it is peculiarly hard that scientific men can accept the distinctions which foreign governments are ready enough to award only as if they were contraband goods. Literature and art are abundantly rewarded in both ways, but, like virtue, science, on which the substantial welfare of the world depends, is its own reward; but this, unfortunately, is not marketable. We trust that the present outcry will lead to a modification of the unreasonable regulation as to foreign orders.

THE "ENCYCLOPÆDIA BRITANNICA"

The Encyclopædia Britannica. Ninth Edition. Vols. vii. and viii. (*Deacon* to *Fakir*). (Edinburgh: A. and C. Black, 1877-78.)

IN the article ENCYCLOPÆDIA, which finds a place in the second of the volumes now before us Mr. Lyons defines an encyclopædia as a book treating of all the various kinds of knowledge. The definition applies well enough to the older encyclopædias, composed when it was still thought practicable to set forth in a single work all that was worth knowing in science and art. To define the province of a modern encyclopædia is a more difficult task, which will probably be avoided by every one who is not compelled either to plan and edit a work of the kind, or to review an editor's plan. Smaller cyclopædias, on the type of the "Conversations Lexicon," naturally limit

themselves to such an abstract of miscellaneous information as may be of service to the ordinary reader. No article is admitted which requires for its comprehension either special preparation or special application. The "Encyclopædia Britannica" aims at something more than this; it addresses itself to the general readers, but it also has a real value for students. On this large plan it becomes very difficult to adjust the respective claims of the two classes to whom the work appeals, and the practical solution must probably be to give what is likely to attract purchasers of a special class without repelling the general public in larger numbers. This seems to be what Prof. Baynes has in view when, along with such articles of general interest as Mr. Freeman and Mr. Gardiner's ENGLAND, he gives us on the one hand an abstruse essay on ELASTICITY, bristling with mathematical formulæ, and on the other a selection of hints for success in playing EUCHRE.

The chief difficulty in successfully carrying out so large a plan lies in the scientific monographs, and more especially in the treatises on subjects which cannot be thoroughly handled without mathematics. In the ninth edition these articles are of a very high class. The editor must be congratulated who, within the two volumes now before us, has articles by Prof. Clerk Maxwell on DIAGRAMS, DIFFUSION, and ETHER, by Sir W. Thomson, on ELASTICITY, by Prof. Cayley on EQUATION, and by Prof. Chrystal on ELECTRICITY. All these are admirable pieces of scientific writing of different kinds. The article Electricity is a singularly clear and well-arranged exposition, which, if printed as a separate volume, would form the best possible text-book for students who are well advanced in pure mathematics. On the other hand Prof. Cayley's account of Determinants and the Theory of Equations is not of the nature of a text-book, but can be appreciated only by those who have some knowledge of the subject. Prof. Maxwell's papers, full of his usual quaint illustration and felicitous turns of expression, sometimes amounting to scientific epigram, would be perfect encyclopædia articles if the ordinary reader possessed accurate habits of thought on physical subjects without actual physical knowledge. But in the present condition of things they are most likely to serve an opposite purpose in clarifying the thoughts of those who have already some reading on the topics dealt with. All these papers suggest the question whether an Encyclopædia of general information ought not to limit itself to articles which can be followed by a painstaking reader who has no other preparation or assistance than he can find in the Encyclopædia itself. Yet, on the other hand, we are grateful to the editor who has opened his pages to so much valuable writing which otherwise might never have appeared at all.

In passing from this topic we may notice, in the article ENERGY, a curious over-statement of the inference to be drawn from the ingenious speculation associated with what are called Prof. Maxwell's "demons." We are told by Mr. Garnett that this speculation "shows that the principle of dissipation of energy has control over the actions of those agents only whose faculties are too gross to enable them to grapple with those portions of matter in virtue of the relative motions or relative positions of which the energy exists with which they are concerned." Mr. Garnett has forgotten the trap-doors which the hypothetical demons command. In fact the simplest form of the hypothesis would be to drop the demons, and make the trap-doors themselves intelligent beings, possessing resistance, and capable of moving without expenditure of energy. Such beings would not be controlled by the law of dissipation, but they would differ from all agents known to observation in a more essential point than the possession of subtler faculties.

Passing over less abstruse branches of science, which are well represented in these volumes by Prof. Huxley, Mr. Wallace, Prof. McKendrick, and other names of mark, we must devote a few sentences to the articles which deal with the history of human life and the movements of human thought. A valuable feature in the editor's plan is the prominence given to subjects connected with the ideas, habits, and traditions of primitive man. In this line we have an excellent article on DELUGE, by Mr. Cheyne, and a very interesting paper on DEMONOLOGY, by Mr. E. B. Tylor. Some of the facts adduced in the latter article may probably need further sifting. We do not think so highly as Mr. Tylor does of Maury's book on magic. Lenormant's work on Chaldean magic must be used with reserve, and, to mention but one other point, the theory of a schism between Indians and Iranians, connected with a change in the meaning of the word *deva*, is open to grave objections. Among properly philosophic papers Mr. Sully's EVOLUTION is valuable from its comprehensive survey of the history of the subject, while Mr. Sidgwick's sketch of the progress of ethical speculation, which may be said to replace Sir J. Mackintosh's dissertation, written for the seventh edition of the "Encyclopædia," gives striking proof of the real advances that are being made in what is often regarded as the most stationary department of human thought.

The articles in Geography, History, and Biography, which to the general reader form the most valuable part of a book of reference, are as a rule very good. Subjects of special importance or attractiveness are treated in these as in the previous volumes by writers of distinguished position and special information, while the minor articles speak well for the diligence and scholarship of the permanent staff. In a few cases material taken over from the last edition might with advantage have been more strictly revised. In conclusion, we would offer one or two hints for this part of the work. It is very desirable that bibliographical references should be as complete and uniform as possible. At present there is considerable inequality in this respect, both as regards the statement of sources of information, and the enumeration in the biographical articles of authors' works and their editions. In such an article as that on DICTIONARY it would be unfair to expect completeness or absolute freedom from error, and one does not complain of such a slip as the reference to Rabbi Iona ibu Ganach's Lexicon as still unpublished, when in reality it has been edited by Neubauer. But an enumeration of modern books upon Ethiopic ought not to have omitted Dillmann's Grammar and Lexicon, and an article on EPHESIANS is not complete without reference to Holtzmann.

There is one other point which a reviewer ought not to pass over. In every encyclopædia there must be a certain

amount of mere compilation by men who have not made an independent study of the subject dealt with. But the public has a right to expect that work of this kind shall not appear with the signature of men of known literary standing. In making this remark we have an eye on Principal Tulloch's article, EUSEBIUS. The whole article is the slimmest literary hack-work, and the notice of Eusebius' works contains mistakes which can be best explained by supposing that the writer was hastily abridging from Smith's "Dictionary," from which several sentences are copied almost word for word. What is said about the "Chronica" is one tissue of error and confusion. The whole work is described in terms that apply only to the second book. The Latin translation of the Armenian version appears to be confounded with the original work, and there is not one syllable to indicate that only fragments of the latter exist. So, again, the "Præparatio Evangelica" is described as a collection of facts and quotations from the works of the ancient philosophers, without any allusion to the important fragments of ancient historians which it embodies. The celebrated Nitrian MS. of the Theophania is said to have been found in an Italian Monastery. And finally, there is no account of the editions of Eusebius, not even of Schöne's great edition of the Chronica.

OUR BOOK SHELF

Cyprus: its History, its Present Resources, and Future Prospects. By R. Hamilton Lang. Illustrations and Maps. (London: Macmillan and Co. 1878.)

THIS, we venture to think, is really the most important and useful contribution to a knowledge of our new dependency that has been published since the surprise was announced. Mr. Lang's long residence in the island and his position there have given him exceptional advantages to acquire a thorough knowledge of it in all its aspects. He has, moreover, made diligent research into the history and antiquities of the classical island, and has succeeded in presenting in this volume a clear and instructive account of these. Mr. Lang maintains that Cyprus must have had a somewhat civilised population before the arrival of either Greek or Phœnician colonists, and that the remains of early writings which have been discovered prove these earlier inhabitants to have been Aryan, and not Semitic, and probably of the same parent stock as the Greeks. About one-half of the work is devoted to the history of the island. In the chapter devoted to agriculture and produce Mr. Lang shows that, in this respect, the capabilities of the island are very large, and that, with improved systems, it might really be made one of the most fruitful of our dependencies. He himself made long experiments in farming, and with the most satisfactory results; and for intending settlers in the island this part of his work will prove of much value. Mr. Lang gives a condensed account of M. Gaudry's researches on the minerals of the island; but our knowledge of its geology is by no means satisfactory, and we trust with Mr. Lang that no time will be lost in getting a thorough geological survey of the island. The chapters on archæology and rock tombs and their contents are of special interest; and of great practical value is the chapter devoted to "my farm in Cyprus." Mr. Lang is very hopeful of the results of this annexation. One of the most interesting results, so far, in our opinion, is his own work on the island. The five beautiful maps by Stanford add much to the scientific value of the work.

Studies in Physical Science. By W. J. Millar, C.E. (London: Marlborough and Co.)

IT is difficult to imagine what want this little book of 102 pages is intended to fill. In form and matter it appears not unlike a schoolboy's notes of some popular lectures. If any one really desires simple and accurate information on the elementary propositions of physical science he can have no difficulty in finding it in the many brief works which have recently appeared from the pens of the foremost authorities on each special branch. What are we to make of the following paragraphs when it is stated in the preface that "the whole has been carefully revised and the most recent scientific views considered"? "The vapours which ascend from the surface of our globe are the channels by which the electricity of the atmosphere is supplied. Evaporation is an active source of electricity, and thus the clouds, which are made up of hollow vesicles of aqueous vapour filled with air, contain a considerable quantity of electricity stored up and ready to be discharged." Concerning the telephone, the author remarks that its "action appears to depend upon the principles of magnetism, electricity, and acoustics." Further quotation is needless.

Hydrostatics and Pneumatics. By Philip Magnus, B.Sc., B.A. (London: Longmans and Co. 1878.)

THIS work forms the seventh volume of the "London Science Class-Book Series," jointly edited by Prof. G. C. Foster and the author of the work before us. The books are intended for "school purposes," but we cannot imagine that the author of the "Hydrostatics and Pneumatics" can be acquainted with science teaching in schools, or its requirements, to judge of his treatment of the question of the relative densities of air at different heights (p. 125), or of the method of finding the difference of height of two stations by means of a barometer, supposing the temperature and force of gravity constant (p. 127). Or again, if we glance at pp. 18, 41, and 58, we perceive at once that the treatment is of far too complex a nature to be taught to young boys in Form who probably have one hour, or at most two, to devote to the subject in a week. For advanced boys in Upper Fifth and Sixth Forms the book will undoubtedly prove useful, provided they can devote several hours a-week in any one Term to the subject. The work is clearly written for the most part, and there are but few omissions. We do not notice, however, any mention of the experiments of Mr. Tomlinson and Prof. Van der Mensbrugge on surface tension, nor of the experiments of Venturi, Bernouilli, and Magnus, on the lateral action of a fluid in motion.

The Bulb Garden; or, How to Cultivate Bulbous and Tuberous-rooted Flowering Plants to Perfection. By Samuel Wood. (London: Crosby Lockwood and Co. 1878.)

IT is not too much to say that the best part of the present book is its cover. The binder has certainly performed his part well, and produced a pretty-looking book, but we must look no further than the cover for a word of eulogy. We have only to turn over the fly-sheet to read the title-page, and we are startled by an extraordinary gaudily-coloured plate, which suggests a design for a patchwork counterpane, but which, upon closer examination, turns out to be one for a bulb garden. With this we are not prepossessed; and the next coloured plate still further lessens our appreciation of the author's artistic taste. We leave the plates and turn to the text, in the hope of finding the literary character of the book such as to make amends for its artistic shortcomings; but still we are disappointed, for, when we find such plants as *Dielytra*, *Tritoma*, *Lychnis fulgens*, the Hellebores, &c., classed as bulbs, we are inclined to ask, Does the author know what a bulb is?

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to ensure the appearance even of communications containing interesting and novel facts.*]

American Exploration

North-western Wyoming and Yellowstone Park

THE letter from Capt. W. A. Jones in NATURE, vol. xviii. p. 667, seems to show a feeling of irritation on his part at the notice of his Report upon a reconnaissance in North-western Wyoming, which appeared in your columns some months ago. There was not in that notice any expression which could be interpreted into a want of recognition of the ability with which he had conducted the operations committed to his charge. Of course the desirability of these operations, and whether they were important enough to justify the expedition, are matters of opinion regarding which we may differ from Capt. Jones, without for a moment casting any reflection upon him. One object of the remarks which have displeased him was to point out the need of some central authority to control the various exploratory surveys in the United States, and prevent a needless expenditure of labour and money in the reduplication of work by parties operating without any concert with each other. This subject was brought before the notice of Congress, and a special committee was appointed to consider it and take evidence. The report of the sittings of this committee shows a most laudable desire of patiently getting at the truth. It recommends that the Engineer Department should not be authorised to undertake any surveys except such as might be required for purely military purposes. Of course, Capt. Jones, as an officer of engineers, thinks this a very "one-sided report." But the decision of the committee met with the approval of the great body of scientific men in America, whose only desire could be the best means of facilitating the thorough exploration of their great country. And the decision was equally welcomed on this side of the Atlantic by men who knew nothing and cared less for the personal bickerings of the different Government departments and surveyors in the United States. Capt. Jones speaks of a quotation made from the committee's report as being "out of the pale of decent characterisation." It was nevertheless the deliberate statement of men who gave their testimony upon oath. Strong expressions of this kind are apt to raise more than a doubt as to the strength of the cause in support of which they are adduced.

With every wish to do full justice to Capt. Jones and his associates, I feel that there is a far larger question behind his complaint than the mere recognition of their contributions to our knowledge of the North American Continent. To students of science in Europe it is a matter of small moment under what Government department or by what organisation of surveying parties the work of exploration is carried on. Most cheerfully do we recognise the labour, the patience, the courage, the physical endurance, the sagacity of observation, and the admirable powers of generalisation which during the last fifteen or twenty years have been bestowed by the various departments upon the task of unravelling the geography and the geological history of vast tracts of the United States. Thus the Department of Engineers has earned our lasting gratitude for the thoroughness and accuracy of its contributions; and had it no other record of its work than the magnificent series of quartos relative to the survey of the 40th parallel, that department would have raised an enduring monument of its scientific prowess. But besides the exhaustive reports of Clarence King and his associates, the Bureau of Engineers has issued many other most admirable volumes, not least among which is that of Capt. Jones himself. Then the Department of the Interior has for a number of years enjoyed the lustre shed upon it by the researches conducted by Dr. F. V. Hayden. Capt. Jones speaks of this distinguished explorer in the generous spirit of a true lover of science. To have succeeded as Dr. Hayden has done means not merely that he has conquered the physical difficulties of unexplored regions, that he has possessed mental powers capable of grappling with the many difficult problems presented by these western territories, that he has that judgment and *bonhomie* which have enabled him to select and keep round him year after year such a band of skilled observers as has included the names of Marvine, Peale, Endlich, and Gardner; but—what, perhaps, demands greater skill and patience than all the rest—that he has had the self-denial and courage to canvass the Congress, and literally persuade or coax its members into granting the necessary appropriations. It is all very well to talk of the dignity of science; but science cannot get on without money; and to get money she must, in America at least, "hiding her dignity in her necessity, be fain to shuffle, to hedge and to lurch." That a man of Dr. Hayden's powers should require to go through this annual penance is sad to think, but, as matters stand, he must either go through it or give up his explorations. He has chosen the former alternative. That in so doing he has done wisely must be granted not only as regards the prosecution of his own operations, but indirectly in reference to the other explorations sanctioned and paid for by Congress. The altogether admirable surveys conducted by Major Powell, for example, also under the Department of the Interior, have a powerful backing in the prestige of Dr. Hayden's work. The Coast Survey has long been a model of accurate and exhaustive methods of research.

Capt. Jones remarks that "in the cause of science a little duplication and reduplication are things not to be sneered at." A few lines further on he says that "exploring is but imperfect work, so far as the survey, which is its foundation feature, is concerned;" and that "observations for longitude with any known portable instruments are painfully erratic, unless there be abundant time." No one ever "sneered at" the repetition of surveys by different exploring parties; but every one, unless perhaps a candidate for future employment in these expeditions, must admit that it is a pity to reduplicate work which is so confessedly "imperfect" and "painfully erratic." Let the first preliminary surveys be made, but let them be done systematically, so that different surveying parties shall work in concert, and not blindly re-survey each other's ground. If any subsequent reduplication can be undertaken let it be again done methodically, with the view of correcting and filling up the first rough outlines. This requires some central controlling authority, and it is the absence of this authority which has led to the misunderstandings and dispeace. At present any man who can gain the ear of Congress, and get an appropriation of so many thousand dollars may go and explore as he pleases, and very much where he pleases, provided only he renders account to the Department of the Interior for the disbursement of the money. Of course this want of supervision leaves the explorer untrammelled by the official bonds which would hamper him if he were surveying in a longer-settled country. He is entirely his own master, can arrange his work and dispose his staff precisely as he judges best for the sake of progress and efficiency. No doubt these are enormous advantages. But then, on the other hand, he must stoop to button-hole the Congress-men, and spend many valuable weeks in getting them to see that they ought to continue, or even to increase their grants to him. He has no departmental organisation behind him on whose support he can rely, and the mere passive existence of which would often of itself be enough for his purpose. He must every year fight his own battle over again against competing organisations, rival explorers, and utterly indifferent members of Congress. It was in this respect that the Department of Engineers proved so formidable an antagonist in the conflict which led to the appointment of the Congressional Committee referred to by Capt. Jones. It is an organised department of long standing with traditions and military *esprit de corps*. The several explorers under its wing had not to stand each with his back to the wall fighting for his own. Their cause was taken up as a general one by the engineers and the army, and it was only after much evidence had been led that the Committee agreed upon that "one-sided" Report which the engineers naturally resent.

If all the surveying work undertaken, or at least paid for, by Congress, were placed under some central control, enough would probably be done were precautions taken to secure that the various operations were carried on in concert and not in utter ignorance of each other, and that the maps and memoirs were issued in some one general form which would facilitate reference. The various explorers need not lose their practical independence. They might remain as unhampered as ever, and be left free to make their own dispositions within certain general limits. Such a central board ought to charge itself with securing the necessary money grants from Congress, and thus save its scientific men from the degradation and loss of valuable time in per-

sonally canvassing the members. The gain to the explorers in this way would surely far more than compensate for any fancied loss of independence.

One word more about American exploration, and it shall be one of unqualified admiration. When a member of any of the branches of the public service in this country which are concerned with scientific publications contemplates the style in which such publications are prepared and issued in the United States, he finds a spirit of envy rising uppermost within him. Quarto after quarto, atlas after atlas, all published in the most sumptuous style as regards paper, printing, engraving, and chromo-lithography, are poured out from the American national press, yet at such prices as not to place them beyond the reach of all but the rich. The number of copies of these costly works actually distributed gratuitously is almost incredible. They are scattered lavishly over Europe, not merely to public libraries, but even to private students of science whose names are known to few of their own countrymen save those who read their writings in the scientific journals. Such open-handed generosity makes many a recipient of the gifts accept them almost with reluctance when he knows how little we in this country can offer in exchange. It is not that we are idle, or that the results of our labours would not furnish materials for important memoirs. But they manage these things better in the States. Perhaps we may profit by their example some day.

ARCH. GEIKIE

Discovery of a Scottish Crannog

WILL you kindly allow me, through the columns of NATURE, to draw the attention of archæologists to a recent discovery of an ancient crannog on the farm of Lochlee, near Tarbolton, Ayrshire. It appears that formerly a considerable portion of what is now arable land, and divided into several fields, was occupied by a loch with mossy banks and bottom, and that about forty years ago its outlet was deepened and its whole area completely drained. When this was done a small mound was observed near the outlet of the lake and about 100 yards from its nearest bank, which, from its artificial appearance and the discovery of two canoes in the bed of the lake, then attracted the curiosity of a few observant people in the neighbourhood, but led to no further result, and soon the whole affair was entirely forgotten. Just now the same locality is being re-drained under the direction of Mr. Turner, factor for the Duke of Portland, and his men, while engaged in cutting the main drain which happened to pass through a small bit of this mound, came upon the peculiar structure of the crannog. Fortunately this came under the cognizance of Mr. James Brown, Tarbolton, who wrote a note to Mr. J. Anderson, Keeper of the Museum of the Society of Antiquaries of Scotland, drawing his attention to this discovery. This gentleman immediately wrote to R. W. Cochran Patrick, Esq., of Woodside, Secretary of the Archæological Society for the counties of Ayr and Wigton, who lost no time in visiting the district, and at once recognised the nature and importance of the discovery. Meantime Mr. Turner and myself made several visits to the locality, in the course of which we observed that three rows of closely-set wooden piles, six feet apart, extended from the mound to the mainland—presumably forming the foundation for a wooden gangway. The tops of these piles, except in a very few instances, are below the surface of the soil. At the same time the men dug up a canoe, in a good state of preservation, hollowed out of one log, and tapering rapidly and uniformly at both ends. It was lying about 150 yards from the mound, and the highest portion of it was three feet below the surface. It measures ten feet long, two feet six inches broad, and one foot nine inches deep. It was then arranged that a careful exploration of the mound should be made, and accordingly systematic excavations were begun on Tuesday last, in presence of Messrs. Turner, Patrick, Anderson, Dr. McDonald, Ayr, and myself, and are now being prosecuted with great vigour and success. As a detailed account of whatever discoveries may be made, together with plans, sections, and drawings of the crannog, will be published in the Collections of the Archæological Society of this county, under the superintendence of its accomplished secretary, Mr. R. W. Cochran Patrick, it is unnecessary for me to give here more than a few remarks, just sufficient to convey to your readers some idea of what has already been done and may yet be expected. Guided by the tops of a few upright piles which just appeared on the surface, a broad trench was dug right round the mound. Some of these piles, all of which were formed of young oak trees, were found to terminate in holes in large horizontal beams, while others appeared to be driven into the muddy bottom and surrounded by thick planks of oak, young trees, and brushwood, amongst which beech, birch, and hazel were readily recognised. On the north-east side, and only about one foot below the surface, were two series of horizontal beams of oak from five to six feet long, and about five feet apart, each of which had two square-cut holes near its extremities, through which upright piles penetrated and were firmly fixed by wedges of wood. These mortised beams rested on round trees which lay horizontally but pointed in various directions. Conterminons with these beams and running towards the centre, there was a rude and very much decayed platform formed of rough planks and saplings lying on large beams of split oak trees. The oozing of water prevented the complete exposure of the mossy bottom on which this curious structure was reared, but it was ascertained to be from seven to eight feet below the present surface. In all the parts that were examined large stones were found interspersed with the woodwork, and the diameter of the foundations of the mound was estimated at about twenty-five yards. A trench was then dug across this circular area, and near the centre we exposed two stony pavements, one lying immediately above the other, the space between being 2½ feet thick. These pavements rested on a thick stratum of clay which extended for several feet all round, gradually thinning towards the rim, and, from the abundant remains of ashes, charcoal, and burnt bones, evidently formed fire-places. About two feet below the lower pavement another layer of clay, together with ashes, charcoal, &c., was observed, and though not yet excavated, we concluded that it must have been a third fire-place. Nearly on a level with this was a layer of chips of wood as if cut by an axe, and underneath this was a layer of turf with the heather part downwards. On pressing the spade still further down it struck a log of wood. The perpendicular height from this log to the top of the upper pavement was seven feet nine inches. All these fire-places were below the level of the water before the first drainage was made. As it is ascertained that previously there was no island to be seen, the whole island must have sunk very much since its original structure. Round these fireplaces were the remains of a series of seven or eight large piles with their bases cut flat and resting on the floor of the middle pavement or a few inches below it. These upright piles inclosed a somewhat circular area, with a diameter varying from ten to fifteen feet. The articles hitherto discovered in the interior of the mound consist of querns, hammer-stones, bone-chisels, and lance-like objects, a spindle-wheel, wooden implements like clubs or paddles, &c., deer-horns, some cut across and marked with holes and other markings, numerous boars' tusks, and a great assortment of bones and teeth belonging to various kinds of animals. With the exception of a singular three-pronged iron instrument found in the large drain outside the mound and a rusty piece of iron shaped like a door-handle, picked up very near the surface of the mound, not the slightest trace of either iron or bronze has been discovered. A piece of red pottery, said by a competent authority to be so-called Samian, found in the same drain and near the same spot as the iron implement above alluded to, and the half of a grooved bead of the size of a hazel-nut and covered with a greenish pigment, are the only fragments of pottery as yet brought to light.

Kilmarnock, October 21 ROBERT MUNRO

Power of Stupefying Spiders Possessed by Wasps

MR. ARMIT's letter, from Queensland, on this subject (NATURE, vol. xviii. p. 642) is, to my mind, of great interest as showing that the habits of insects are the same at the antipodes as on our side of the globe. I was well aware that the spiders were stupefied (or paralysed) and not killed, and that the use made of them by the wasp was as a nidus for her ovum, and to serve as fresh provisions for her larvæ when hatched. Of course if killed they would be useless for this purpose. We have a wasp of similar habits, but he makes use, in the cases in which I have watched his operations, of the larvæ of the garden white butterfly, which are rendered passive and helpless, but not killed, in a similar manner.

I make alternative suggestions for further, and if possible microscopic, examination into the matter. First, are the wounds producing this insensibility inflicted with the sting, or by an ovipositor in the act of inserting the ovum? Is the egg in the case of the wasp, as with the ichneumon, inserted in the insect to serve by and by as food, or outside it, in the cell? If

the latter, then the punctures are, no doubt, true stings; and I make the alternative suggestion that the wasp is guided by its instinct—as the larva of the ichneumon is when feeding—to select for attack parts of its victim not vital, where the injected acid produces insensibility or partial muscular paralysis, but not death. Because in the rare cases in which a wasp or bee struggling in a spider's web succeeds in stinging his captor, in anger and at random, the spider dies. May the observation made in your columns by a recent correspondent, on the self-administration, through the mouth, of the poison of the sting by wasps and bees under chloroform not point to a stupefying property in the acid when taken, as the natives of India take the poison of venomous snakes, into the stomach, and not directly into the circulation of the blood? There is good work here for an observer with patience and a good field microscope.

Bregner, Bournemouth, October 19 HENRY CECIL

A Fossil Plant—Misquotation

IN an article on a fossil plant from the Isle of Man, in NATURE, vol. xviii. p. 555, the following sentence is attributed, apparently on the authority of Mr. Leo Lesquereux, to my report on the Devonian and upper silurian plants of Canada: "that these fragments are probably originating in the upper silurian of Gaspé; that as they are found in the lower part of the limestone which underlies the Devonian Gaspé sandstone and become more abundant in the upper beds, this suffices to indicate the existence of the neighbouring land, probably composed of silurian rocks and supporting vegetation."

On referring to the report in question, I find that the original of this strange statement stands as follows:—

"These remains of *Psilophyton* occur in the lower part of the limestone, but are more abundant in the upper beds, and they suffice to indicate the existence of neighbouring land, probably composed of lower silurian rocks, and supporting vegetation."

I have no doubt that Mr. Lesquereux quoted from memory, and probably supposed that he was expressing my meaning, but an English writer should have referred to the original.

I may add that the specimen referred to in Mr. Binney's article does not exhibit the characters of my genus *Psilophyton*, which does not contain "fucoids," but land plants of the rank of acrogens, and of which not merely the external forms, but also the internal structures are described and figured in the report referred to. The plant in question much more closely resembles *Buthotlephis harknessii*, Nicholson, from the Skiddaw slates. J. W. DAWSON

McGill College, Montreal, October 5

Sense of Fear in Chamæleons

DURING the past summer I have kept five chamæleons in captivity, and have repeatedly observed their terror and rage when confronted with snakes. When a large Algerian chamæleon (*C. vulgaris*), now in my possession, perceives a common snake (*Tropidonotus natrix*) wriggling in his vicinity, he at once inflates his body and pouch, sways himself backwards and forwards with considerable energy, or walks rapidly away with his body leaning over in the direction furthest from the snake, opening his huge cavernous mouth, and hissing and even snapping at what he evidently regards as his natural enemy. At the same time his body assumes an almost instantaneous change of colour, and is quickly covered with a large number of small dark brown spots. It is curious that similar symptoms of fear and anger are displayed when a lizard (*Lacerta viridis*), or even a tree-frog (*Hyla arborea*) is exhibited to him. The climax of grotesque nervousness was, however, reached one day, when the sight of a child's doll produced the like effect; in this case, it is probable that the glass eyes of the doll, giving to it the appearance of life, were what caused this terror in the reptile.

R. MORTON MIDDLETON, Jun.

West Hartlepool, October 23

An Unusual Rainbow

OCTOBER 28 was a fine day with a brisk westerly wind blowing. At 2 P.M. a splendid well-defined nimbus cloud passed from north-west to north-east, about a mile to the north of this observatory, and rapidly driving away before the wind, left a large tract of cloudless sky behind it, the sun shining at the time. Suddenly at 2.12 P.M. a magnificent rainbow shone out most brilliantly across the blue space, the effect being exceedingly novel and charming. The veil of rain-drops forming the bow was so thin as to be invisible except near the zenith, where there appeared to be a thin cirrus. No rain fell on the observatory, and unfortunately there were no means of determining subsequently the area covered by the shower.

Eventually the rainbow faded away over the cloudless sky, and the 30° or so of the extreme eastern end which overlapped the receding nimbus shone out with a vivid brightness until it disappeared.

A secondary bow was not visible in front of the clear sky, but the violet band of the primary stood out with great distinctness, apparently separated from the remainder of the bow.

Kew Observatory, October 29 G. M. WHIPPLE

OUR ASTRONOMICAL COLUMN

A MISSING STAR.—There was a curious, and at the time suspicious, history attaching to an object, shining as a star of 9·10 magnitude, which was compared on several nights with the minor planet *Hygeia*, while under observation at Washington in the autumn of 1850. This star, which was designated *k* in a list published in Gould's journal, was missed by Mr. Hind, who reported the circumstance in a letter to Mr. W. C. Bond, of Harvard College, by whom the attention of Lieut. Maury, at that time superintendent of the Naval Observatory, Washington, was called to it. Mr. Ferguson having verified the disappearance of this object on August 29, 1851, a search was made for it on the assumption of it being a great planet exterior to Neptune; the reason for this assumption will be apparent from an inspection of the following positions, which result from the observations on three evenings:—

1850.	Washington Mean Time. h. m. s.	Right Ascension. h. m. s.	Declination. ° ′ ″
Oct. 16	6 52 36	19 17 42·81	−20 44 57·1
,, 21	7 6 40	19 17 42·19	−20 44 55·5
,, 22	6 35 35	19 17 43·90	−20 44 54·6

It was also observed on the 19th, but the accurate positions of the stars of comparison are not available. These observations appear to indicate that the object had motion in R.A., but that it was stationary at some time between October 16 and 22, and if we suppose it to have been a planet moving in a circular orbit, we find to allow of its being stationary at this elongation from the sun, its distance would be 49·94, and its period of revolution 351 years, or about twice the period of Neptune, and the period of Neptune is about twice that of Uranus. Notwithstanding the search was continued from August 29 to December 11, 1851, and extended to all stars of the eleventh magnitude between 19h. 20m. and 19h. 36m., and from −19° to −21° 20′, no planetary body was found. That the Washington observers considered suspicion to attach to the object is obvious, but the only likely explanation appears to be that there was a variable star in this position, and that the observations in right ascension were affected with greater error than might be expected, considering that on two of the days of observation several comparisons were made. To our knowledge search was also made in Europe for the Washington star. Further particulars will be found in two letters from Maury, published in Gould's *Astronomical Journal*, No. 36.

THE SATURNIAN SATELLITE MIMAS.—From some Washington observations of this difficult object between the years 1874 and 1877, it appears that the following elements may be taken as approximately representing the motion of the satellite in the interval on the assumption of a circular orbit in the plane of the rings: epoch 1878, January 1·0207 G.M.T., $u = 0° 0'$, $N = 126° 14'·5$, $I = 7° 3'·2$, radius of orbit at the mean distance of Saturn 27″·40, period of revolution 22h. 37m. 5·614s., or the logarithm of the period in days = 9·9742473. The

general run of the differences between calculation and observation, incident probably in part to a sensible excentricity, may be judged from the following results of comparison with a few of the observations made with the great refractor at Washington :—

	Pos. $(c-o)$	Dist. $(c-o)$		Pos. $(c-o)$	Dist. $(c-o)$
1874 Sept. 2	$+0°.6$	$+0''.28$	1877 Aug. 11	$+0°.9$	$+1''.13$
,, ,, 26	-2.6	-0.54	,, Oct. 15	$+0.5$	0.00
,, Oct. 15	$+0.2$	0.00	,, ,, 16	-1.2	...
1876 Oct. 13	$+1.2$	$+0.45$	,, ,, 17	$+4.1$	$+1.86$
,, ,, 31	-1.3	$+1.33$			

From the above elements we shall find for the times of greatest elongation of Mimas eastward, 1878, October 31, at 10·4h., November 1 at 9·0h., November 2 at 7·6h., and November 3 at 6·2h., and at these times, the distance of the satellite from the centre of Saturn about 30″.

GEOGRAPHICAL NOTES

ADVICES from Mr. John Carnegie, H.B.M. Consul at Loanda, of September 9 ult., give most encouraging news with respect to Mr. Heath's expedition to Angola. The young explorer had enjoyed excellent health and had just started on a six months' expedition up the River Bengo, proceeding to Galungo Alto, and, if his health permitted, returning by the Quanza River. The first small collection of birds has been received from Matamba, on the Rio Bengo, an account of which will shortly be laid before the Zoological Society by Mr. Bowdler Sharpe. As the result of a first month's collecting it is creditable, but the season of the year having been adverse, nothing of any striking interest is contained in it. More may be expected from the large case of specimens now on its way to England.

MANY attempts have been made to penetrate into the interior of Greenland from the west coast, but, until this summer, with little success. Three Danish gentlemen, Messrs. Jensen, Kornerup, and Groth, under the direction of the Commission for scientific exploration in the Danish colony, started to explore and survey the coast between Godhaab and Frederikshaab. Lieut. Jensen took advantage of the opportunity to make an excursion into the interior over the ice. The aim was to reach several mountain peaks rising out of the ice. The baggage was placed in three small sledges of the travellers' own, and the toilsome journey commenced on July 14. After two days the loose snow accumulated on the surface of the ice to such an extent that the journey became very dangerous, while they continually sank in concealed crevasses and holes, saving themselves only by adopting the Alpine expedient of attaching themselves to each other with a rope. The surface of the ice was generally undulating, but there were also many rugged parts and chasms, which rendered the journey a very difficult one. It was foggy nearly the whole time, and on July 23 a snowstorm came on. On the 24th the expedition reached the foot of the mountain referred to above. Then came on another storm which lasted for six days with continuous snow and fog; the travellers were snow blind. The weather cleared on the 31st, when the ascent of the mountain might be undertaken with some prospect of success. The height was estimated at about 5,000 feet above sea level, and on the other side of the mountain, as far as the eye could reach, ice sheets and glaciers were seen, and not the smallest speck of land free of ice. After finishing their observations the expedition returned, and reached their starting-point on August 5, having been away for twenty-three days. The mountain referred to was forty-five miles from the coast.

THE discovery of a new island in the Polar Seas is announced. E. Johannessen, who has just returned to Tromsö, reports that he penetrated a considerable distance to the east, beyond Novaya Zemlya. On September 3, in long. 66° E. and 77° 35′ N. lat., he discovered an island which he has named "Ensomheden" (loneliness). It is about ten miles long, and level, the highest point not exceeding 100 feet. It was free from snow, with poor vegetation, but an immense quantity of birds. The sea was free from ice towards the west, north, and south, but drift ice was seen towards the south-east. There was evidence that the Gulf Stream touched the west coast of the island; the Stream runs in a strong current round the north coast towards the south-east. Everything about the ice was favourable for navigation so long as the vessel did not go too near the mainland of Siberia. The newly-discovered island lies, therefore, somewhat to the south-east of the region visited by the Austrian expedition of 1873-4. It has been thought probable that a line of islands in the latitude of this island extends along the north coast of Asia.

NEWS has been received from Prof. Bastian, of Berlin, that he safely arrived at Bushire, on the Persian Gulf, *via* Teheran and Ispahan, and that he has thence continued his journey by sea.

LIEUT. SANDEBERG, whose explorations in the Kola Peninsula and the White Sea we have already referred to, has returned to Sweden with numerous zoological collections obtained during the past summer. Lieut. Sandeberg finds the coast-waters between Varanger Fjord and the White Sea extraordinarily rich in cod and whales.

THE *Deutsche Geographische Blätter* of the Bremen Society, No. 4, contains several items of interest, some of which we note separately. There is a long and valuable paper by Prof. Struder on a visit he made to Timor in 1875, and another on the results of the numerous voyages to Siberia made this summer, all of which have been so eminently successful that a regular summer trade-route to the great Siberian rivers may now be held as established.

THE *Bulletin* of the Geographical Society of Marseilles for July–August contains an interesting account of the little-known Island of Lamoo, on the African coast, a few degrees north of Zanzibar. The island itself is described, and a pretty full account given of its inhabitants and their habits.

A TELEGRAM from Hong-Kong states that the Chinese authorities are contemplating the construction of a railway from Taku to Tientsin, in order to facilitate communication with the capital and to avoid the difficulties to navigation caused by the tortuous course of the Pei-ho. A rumour from the north in regard to this scheme was published in the *North China Herald* of Shanghai, on August 10, "with all due reservation," as it appeared almost too good to be true. Our contemporary says that the plan is believed to have been agreed upon last year, but delayed in execution because it had been hoped that the plant of the condemned Shanghai and Woosung railway could have been made partly available for the purpose. This having been otherwise disposed of, it is said to have been now determined to purchase new plant throughout, and to press forward with the new line as quickly as possible. Mr. Tong Kingsing, a well-known Cantonese merchant, frequently employed by Li Hung-chang, who is said to be the prime mover in this matter, has been at the coal-mines in the north-east of the province of Chihli for some time, but he is expected to return to Tientsin shortly, when it is believed that immediate steps will be taken concerning the new line.

THE Society of Geography of Paris held its first meeting for the year 1878-1879 on Wednesday week, in its new hotel, Boulevard St. Germain, No. 194. The number of members present exceeded 200. M. Quatrefages, president of the Section Centrale, was in the chair, and gave an address, in which he congratulated his fellow members

on the success obtained in the building of the lofty mansion in which they were assembled, which is at a little distance from the place where the Society was founded in 1821.

In his just-published report to the Foreign Office on the trade and agriculture of French Guiana, Consul Wooldridge forwards some information of considerable interest in regard to the production of gold in that region. The quarter of Mana, hitherto unknown as a gold-producing territory, has, through the energetic endeavours of adventurers, been prospected, and is speedily being opened up; indeed, it promises to be one of the richest gold industrial quarters. The production of gold at a few hastily-established placers, in the month of March last year, gave 21,747 grammes of pure gold, and in April 39,662 grammes. It is to be feared, however, that the gold-workings here and in other parts where the precious metal is found to a large extent is having a disastrous effect on the general prosperity of the colony, for Her Majesty's Consul, quoting from the report of the Commission which periodically proceeds to the various quarters to inspect estates, draws a melancholy picture of the abandonment and poverty of agricultural property in French Guiana.

The latest work of the leader of the Austrian North Polar Expedition, Captain Karl Weyprecht, entitled "Die Metamorphosen des Polareises," is now in course of publication at Vienna (Perles).

A curious statement appears in the foreign correspondence of the *Times*, that Russian papers state that the Amu-Darya has returned to its original bed. This may very well be the case without any or much interference on the part of man, as may be seen from Major Herbert Wood's articles on the Aral region in vols. xi. and xii. of Nature. About twenty years ago the Loodon Canal at Bend, above the splitting up of the lower Amu, was dammed up. This canal seems to have been connected with the old course of the Amu into the Caspian, and a strong flood breaking down the dam might easily cause the river to resume its old course, especially as its present mouths seem to be gradually filling up with the abundant matter brought down by its waters. It is apparently at Bend that the deviation has taken place.

An able review of Geography at the Paris Exhibition appears in the last number of the *Revue Scientifique*.

THE TELEPHONE, ITS HISTORY AND ITS RECENT IMPROVEMENTS[1]

I.

The appearance of the two works mentioned below is indicative not only of the remarkable era of scientific invention through which we are passing, but also of the wide-spread interest in science which these inventions have aroused.

It will be noticed that neither of these works is published in England: one reaches us from America, the other from France. As a nation we are slow to appreciate the value of new inventions—a conservatism which arises less from caution than from popular ignorance of science; nor will an enlightened public opinion be possible until the first principles of science form an integral part of the education of every English boy and girl. But now that science is walking in the market-place, and holds its own on the exchange, ignorance of its elements becomes commercially perilous. A sound judgment on the value of a new scientific discovery may at any moment be indispensable to capitalists and very profitable to shareholders. We venture to say that such a conviction has been a prevalent idea on almost every stock exchange during the recent panic in gas shares. Scientific knowledge has presented itself in a new light: it is now a commercial article; and forthwith the British public promptly recognises its value. In fine, the business aspect of recent inventions may do more for the future extension of science teaching than years of earnest expostulation.

The two works before us cover nearly the same ground. They give the history of the invention of the telephone, the methods that have been devised for electrically transmitting and receiving speech, with the most recent improvements down to a month or two ago; they also describe the phonograph; and Prescott's book, while omitting the microphone, which is fully discussed by Du Moncel, devotes its concluding chapters to quadruplex telegraphy, electric call-bells, and electric lighting.

Of the two works Count du Moncel's is the more scientific, comprehensive, and impartial, and will add to the high reputation which its indefatigable author already possesses as the historian *par excellence* of the applications of electricity. We can therefore most heartily commend this treatise to our readers; it is, moreover, well printed, capitally illustrated, and withal published at a very low price.

Mr. Prescott's work is larger, the typography and illustrations are excellent, and in technical details and recent information it leaves nothing to be desired. The arrangement, however, is confusing. The body of the work consists almost wholly of reprints from the various papers, lectures and specifications of the workers at electric-telephony, and the absence of marks of quotation with the want of proper indication where one extract ends and another begins not only puzzles the reader but is apt to give rise to serious misapprehension. The work has obviously been hastily prepared for the press, repetitions are frequent, and the matter is arranged with little regard to the reader's convenience or to chronological sequence. Moreover, its author has an evident bias towards American inventions in general and the "Western Union Telegraph Company" in particular. It is true the work professes to deal with speaking telephones only, but as some American "tone telephones" are described in detail, we are surprised at the entire omission of the early and important telephonic experiments by Cromwell Varley in London, and afterwards by La Cour in Copenhagen.

Nevertheless, with all its defects, Mr. Prescott's book is a useful and needed contribution to scientific literature, and as each inventor is allowed to speak for himself, the careful reader is enabled to form his own judgment on certain disputed questions of priority of invention.

It is time that the history of the articulating telephone was written. Hitherto the English public have had little more to guide them on this subject than the lectures given in London by Prof. Graham Bell, lectures delivered with altogether admirable grace and diction. It is very natural that an inventor should give more prominence to his own ideas than to those of others, and hence the impression generally derived from Prof. Bell's lectures is that the sole credit of the first conception and successful construction of the articulating electric telephone is due to himself. There were, however, other workers in the field of electric-telephony besides Mr. Graham Bell, and it is to be regretted that Prof. Bell did not give sufficient prominence to this fact in his discourses. Mr. Prescott, indeed, brings some serious charges against Prof. Bell, asserting that to another American, Elisha Gray, of Chicago, is due the entire priority and merit Bell claimed for himself. Here is what Mr. Prescott says:—

"It was not till after Prof. Bell had substituted the apparatus shown in Mr. Gray's *caveat* that he was enabled

[1] "The Speaking Telephone, Talking Phonograph, and other Novelties," by G. B. Prescott. Illustrated. (New York: Appletons, 1878.)—"Le Téléphone, le Microphone, et le Phonographe," par Le Comte Th. du Moncel. (Hachette, 1878.)

to successfully accomplish the grand object of reproducing articulate speech at a distance" (p. 73).

A little further on Mr. Prescott remarks :—

"From the reading of the text [Prof. Bell's lecture in London] it might be erroneously inferred that the apparatus shown [a water variable-resistance telephone] was invented by Prof. Bell, and exhibited by him at the Centennial Exhibition. Prof. Bell neither invented nor exhibited it. The figure [given by Bell] represents the transmitting portion of Elisha Gray's original speaking telephone, the first articulating telephone ever invented. Mr. Gray experimented with the telephone at the Centennial Exhibition in America in 1876, and showed it, among others, to Prof. Barker, but did not exhibit it to the judges."

Even with reference to the present shape of Bell's telephone, Mr. Prescott denies that Bell was its inventor and he adduces evidence to show that the present portable form of the handle telephone was due to Dr. Channing and Mr. Jones, of Providence, R.I. This, however, is a minor matter, but the question of priority of invention of the principle of the articulating telephone is one of general interest and importance.

To the consideration of this matter the Count du Moncel brings not only an independent and unbiassed mind, but also a profound technical and historical knowledge of the various applications of electricity. And in the following opinion, which he expresses, we entirely agree :—

"Si M. Bell a été le premier à construire et à rendre pratique le téléphone parlant, M. Elisha Gray avait le premier conçu le principe de cet instrument et l'avait combiné en electricien consommé."

A similar opinion is expressed in a very able and lucid discourse by a well-known electrician, Mr. F. L. Pope, delivered last December before the American Electrical Society at Chicago, reprinted in Prescott's book. At the same time we must bear in mind Prof. Graham Bell had for some time back also been at work at a similar problem to that which had led Gray to the conception of an articulating telephone, namely, the problem of multiple telegraphic transmission by means of harmonic vibrations, and from this subject was led to the discovery of his magneto-electric telephone. As Mr. Pope remarks, "when we consider that each was working in ignorance of the labours of the other, the singular coincidence in the results they finally obtained is not a little remarkable." To Gray and Bell a third name has also to be added, namely, that of Edison, to whose work we shall refer more fully in another article. These three names stand conspicuously forth in connection with the discovery of the speaking telephone, and we therefore propose to trace the relationsbip each bears to this subject.

The dominant idea that stimulated each of these inventors was the possibility of transmitting several messages simultaneously along one wire. By his patent of 1870 Varley had led the way to the method by which this could be accomplished; he succeeded, in fact, in transmitting secondary currents, generated by the vibration of a tuning fork, in the primary circuit of an induction-coil, concurrently with the ordinary Morse signals, the former not sensibly affecting the usual electro-magnetic receiving apparatus, but producing audible signals on a peculiar receiver of his own. After this, in September, 1874, La Cour, of Copenhagen, patented an apparatus for multiple transmission, founded on a modification of Varley's plan. In this case the receiver was a tuning-fork, controlled by an electro-magnet, and tuned in unison with the transmitting fork, hence it was capable of being thrown into sympathetic vibration by the electric waves started by the latter. A series of such duplicate forks was employed corresponding to the notes of the musical scale, and it was found that the intermittent currents of several of these forks could be simultaneously transmitted without confusion, each receiver selecting and vibrating under its appropriate system of electro-magnetic impulses. Early in 1875 Gray, of Chicago, patented a somewhat similar, but more perfect arrangement. Gray's caveat, or application for his patent, dates from August, 1874, so that in point of fact he anticipated La Cour's method. Instead of using tuning-forks Gray employed strips of steel as being lighter and more sensitive; each transmitting reed instrument had, of course, its fellow at the receiving end, which promptly responded to its own system of waves, acting upon it through an adjacent electro-magnet.

The idea of synchronising the movements of two instruments at wide intervals apart by employing the principles of isochronous vibration is not novel, it was carried out by Helmholtz in his experiments on vowel sounds; and still earlier distant isochronous pendulums were used in telegraphy to control machinery, by Vail, in 1837, Ronalds in 1861, and Hughes in his printing-telegraph. But Gray accomplished more than this. Reiss, in 1862, had shown by his telephone how the *rate* of vibration might be electrically transmitted and reproduced, but the amplitude and mode of vibration were lost; Gray, towards the close of 1874, discovered a method whereby the proper *amplitude* of each vibration or combination of vibrations could be reproduced, "by causing the effective strength of the electric current, by which the transmission is

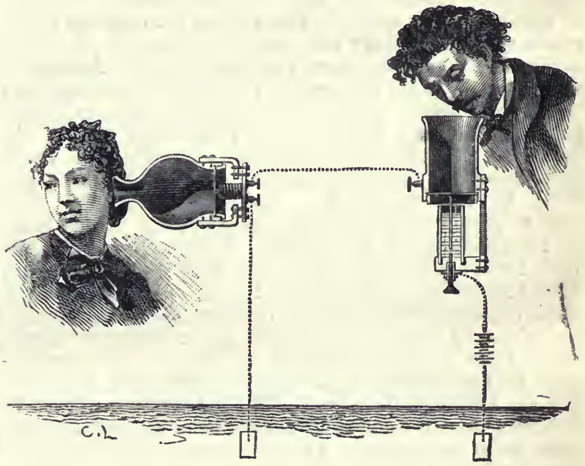

FIG. 1.—Original arrangement for the electric transmission of speech designed by Gray. A current from the battery on the right passes into a vessel containing water, into which dips a wire attached to the vibrating membrane and in circuit with the line. (From Du Moncel's work.)

effected, to rise and fall with the varying amplitude of the sonorous waves which are to be reproduced." Hence, as Mr. Pope, in the discourse to which we have alluded, goes on to remark :—"This having been accomplished, it was not difficult to foresee that two practical applications might be expected to follow, namely, multiple transmission and vocal transmission."

There yet remained however the difficulty of impressing upon an electric current the rapidly-changing *forms* of the sonorous waves which occur during the act of speaking. In the beginning of 1876 Gray conceived the idea of accomplishing this by attaching to a stretched membrane, such as was used by Reiss, an arrangement whereby the movements of the membrane should produce proportional alterations in the resistance of an otherwise constant electric circuit. Undulatory currents of fluctuating strength would thus be set up by the voice, and these, acting electro-magnetically upon a diaphragm at the far end—to which was attached a piece of soft iron—would cause it to be thrown into vibrations corresponding to those existing at the transmitting end. The problem of the transmission of speech was thu

theoretically solved. On February 14, 1876, Gray registered this invention at the American Patent Office, under the title of "a means of transmitting and receiving vocal sounds telegraphically," and in his caveat he gives an exact drawing of the method he adopts, and which we here reproduce.

Curiously enough, on the very same day, there appears the first documentary evidence on behalf of Prof. Graham Bell, and this, too, is for a patent granted to Bell—not, however, for the electric transmission of speech, but "for certain new and useful improvements in telegraphy." These improvements consist in the employment of *induced* undulatory electric currents, and form one of the numerous practical applications of Faraday's famous discovery of magneto-electric induction. By the approach and recession of the prongs of a magnetised tuning-fork, or by the oscillation of a magnetic diaphragm, alternating currents were generated in an adjacent coil of wire. This is the essence of Bell's patent, the advantages claimed by the use of such undulatory currents being increased speed of telegraphy and the possibility of multiplex telegraphy. Nothing is said about the transmission of speech till near the end of the specification, when it is stated that "one of the ways in which the armature may be set in motion [to generate these currents] is the wind. Another mode is the human voice, or by means of a musical instrument." So that, of the five claims made by this patent, the last, and apparently quite subsidiary one, was "the method of transmitting vocal or other sounds telegraphically." A diagram of the arrangement devised for this purpose accompanies the specification, which arrangement, however, upon subsequent trial, proved, as Prof. Bell stated in London, "unsatisfactory and discouraging." It is not, however, fair to conclude, as Mr. Prescott has done in the words we quoted earlier, that Bell had to resort to Gray's method before he was enabled to transmit speech electrically. The fact seems to be that some little time after he obtained his patent, Bell turned his attention to the development of the speaking telephone, and by a modification of the method he originally proposed, arrived at some important results which were published on May 10, 1876, in the *Proceedings* of the American Academy of Arts and Sciences. Sir W. Thomson heard articulate sounds transmitted by this telephone in August, 1876, but the instrument was then very imperfect, nor was it until the early part of 1877 that the speaking telephone may be said to have been a *fait accompli*; in May, 1877, it was successfully tried between Providence and Boston, places forty-three miles apart. There seems reason to believe that the important improvement of the substitution of permanent magnets for electro-magnets was made at the suggestion of Prof. Dolbear, and that Professors Peirce, Blake, Channing, and others contributed valuable modifications of the original design, until the Bell telephone assumed its present simple, elegant, and handy shape, growing in efficiency as it diminished in size and complexity.

Thus it will be seen both Gray and Bell can fairly claim the discovery of the principle of the articulating electric telephone. Gray solved the problem first theoretically, Bell first practically; the former proposed to vary the resistance of the circuit without changing the electromotive force; the latter varied the electromotive force without changing the resistance. And although Gray's method was only partially successful in operation, owing to his employing an electrolytic resistance, it is a method capable of yielding more striking results, owing to the use of more powerful currents. But where Gray failed, Edison has succeeded, and in another article we propose to trace the connection of this remarkable inventor with the subject of electric-telephony, up to his splendid discovery of the carbon telephone.

W. F. BARRETT

COLOUR BLINDNESS IN RELATION TO THE HOMERIC EXPRESSIONS FOR COLOUR[1]

II.

SO far as I can follow Mr. Gladstone's investigations, it appears to me that Homer has exactly fulfilled all the conditions mentioned in the previous article. As many references are made to natural objects which have the same colours now as they had in his time, I am able, with my colour-blind experience, to judge what sensations they would present to his eyes, supposing him colour-blind, and I can thus form a judgment of the appropriateness and consistency of his descriptions on that hypothesis. I can clearly trace the existence of two groups of epithets, which, so far as I can see, are kept fairly distinct, and the words in which are never mixed up with the ideas belonging to the contrary group. The epithets are—

For the group of the yellow sensation: ξανθός, ἐρυθρός, φοίνιξ, ῥοδόεις, χλωρός, κυάνεος, and perhaps οἶνοψ.

For the group of the blue sensation: πορφύρεος and ἰοειδής.

For neutral sensations, irrespective of the words λευκός and μέλας (which may be left out of consideration altogether, the use of them being normal, and the vision of the colour-blind in regard to them being normal also) there is the epithet πολιός, on which an important element of the argument hangs.

We will now take these various words *seriatim*, and compare what Mr. Gladstone says of their application with the use that might be expected to be made of them by a colour-blind writer.

Ξανθός.

Liddell and Scott's translation of this word is "yellow of various shades, often with a tinge of red, chestnut, auburn." Mr. Gladstone (N. 380) considers it, as used by Homer, to be a true word of colour, and that its applications are especially consistent.

It is used principally for human hair, and to the colour-blind *all* varieties of hair, except such as is positively jet-black, appear shades of yellow. Fair or golden hair is a light yellow, red and auburn hair are deeper tones, more intensely coloured, and all varieties of brown are darker still.

The word is also used for the colour of horses. All the varieties of chestnut and bay are to the colour-blind dark yellow, a yellow brown, the former of a lighter, the latter of a darker shade.

Ἐρυθρός.

This is, I suppose, the most usual Greek word for red. Mr. Gladstone (N. 375) takes it to be the best approach to a true genuine colour-epithet, but at the same time he remarks how strange it is that Homer's idea even of red does not seem to be wholly distinct.

The difficulty, however, vanishes if we suppose Homer to have been in the position of the colour-blind, to whom, as I have explained, the proper idea of red is unknown. The word, according to Mr. Gladstone (N. 375, H. 460), is applied to copper, nectar, wine, and blood, all which, though they may differ in appearance to the normal-eyed, present to the colour-blind only different modifications of the yellow sensation.

In regard to blood, the hue varies according to its condition, arterial blood differing materially from venous blood in its colour. I believe that normal-eyed people hesitate to recognise any yellow element in it in any condition, but it is quite certain that when bright and freshly-oxygenated, it presents a sensation of yellow to me; and this is consistent with the fact that its colour is said to be chiefly due to the oxygenation of the iron it contains, the peroxide of iron being to me very positively yellow.

I conceive it may be possible that in this, as in many

[1] Continued from p. 679.

other cases of red, the yellow element may really be there, but may be so overpowered, to the normal eye, by the more vivid red sensation as to be undistinguishable to them, whereas to me, who am free from such interference, it is distinctly visible.

When blood is in the venous state it alters its colour, losing the yellow and acquiring the blue; and I believe normal-eyed people admit the existence of the blue element in blood of this kind. This fact will be found of importance in a subsequent place.

Mr. Gladstone adds:—"The favourite use of the word is for wine; this is very remarkable, because wine is not of a redness proper, but only approximative, and with a decided infusion of the idea of darkness." He also notices its application to the dark hue of red sandstone rock, and sums up by saying that the word is, in the great majority of instances, associated with dark rather than with bright. This is quite in accordance with the darkening idea of red that pervades the colour-blind theory.

Φοίνιξ.

This word is translated by Liddell and Scott, "a purple red, purple, or crimson." It is used very frequently by Homer, and Mr. Gladstone (N. 372, H. 463) finds many difficulties from its being applied to colours materially different from each other. If, however, we test his examples by the dichromic perceptions, we shall find all the difficulties disappear.

The first application is to blood; and in this case the word would appear to be synonymous with *eruthros*, and is justifiable on either the normal or the colour-blind principle.

But it is also applied to the colour of a horse, who was *phoinix* all over except a white spot on his forehead. Mr. Gladstone says that the same epithet sits very ill upon blood and the colour of a horse, whether bay or chestnut; and no doubt this is true as far as normal-eyed people are concerned, inasmuch as the equine hues contain, I am told, a much larger amount of yellow, being, in accurate colour terms, different varieties of orange-brown. But to the colour-blind these present only their yellow element, and since it is by that same element that arterial blood is recognised, there is no incongruity in the person describing both by the same term. It is curious that, whereas in the case of blood *phoinix* is used as a synonym for *eruthros*, in the case of horses it is used as a synonym for *xanthos*—a strong presumption in favour of the *grouping* I have insisted on—the combination being justified through the common element of yellow.

Phoinix is also used for the back of a dragon or serpent, for jackals, and for the skin of a lion. The lion is, even to normal-eyed people, exactly my colour, yellow brown, and the jackal, though grey or variegated on the back, has much of the same hue about him. I never saw a dragon; but snakes vary much in colour, and at least half the varieties at the Zoological Gardens convey to me a positive impression of yellow.

A compound of the word is also applied indirectly, by a comparison with the serpent (H. 476) to the rainbow. For the explanation of this, see the word *porphureos* farther on. It is also applied to cloaks or mantles, which Mr. Gladstone concludes were not red, as Homer never applies to them the more positive epithet for that colour. As we do not know what hue they were, we cannot reason on this application: it is sufficient for my purpose to assume they may have been some of the many varieties of colour which would give the yellow sensation to the colour blind.

It is applied to the bows of ships, which are known to have been painted with some kind of red colour.

If the word *phoinix*, used in *Od.* vi. 163 to mean the palm tree, has any connection with the colour epithet, as Mr. Gladstone appears to suggest, it furnishes a startling addition to the proof of the colour-blind theory. The confusion of red and green is incomprehensible to the normal-eyed, but it is one of the best-marked symptoms of the dichromic malady. *Phoinix* to me would just as correctly represent the leaves of a palm as it would arterial blood, a chestnut horse, or the skin of a lion.

It is clear, therefore, that we have only to suppose *phoinix* to be one of a group of words, all representing the colour-blind sensation of yellow in some of its varied shades and tones, and the whole of these apparently strange and anomalous applications become natural and justifiable. Indeed, Mr. Gladstone (H. 455) notices the anology with *xanthos*, and remarks that *phoinix* appears merely to "render other words."

Ῥοδόεις.

Referring to the rose; rosy. In noticing the use of this word, Mr. Gladstone (N. 376) at once seizes on the remarkable fact that, although the redness of the rose is so obvious, yet "there is no direct point of contact between Homer's expressions taken from the rose, and *eruthros*, as they are never applied to the same objects."

But this is perfectly in accordance with the sensations of the colour-blind. It was pointed out long ago by Dalton, and I took some trouble to explain the fact scientifically in my paper, that "Crimson and pink (rose colour) appear to have no relation to the idea of red derived from vermilion or a soldier's coat;" and if the colour-blind person has been in the habit of using *eruthros* for the latter it would do violence to his sense of colour to use it also for the rose. This flower, beautiful and positive as its colour is to the world in general, gives to me a very vague impression. Its characteristic of redness being invisible to us, we see in most cases only a pale grey; if the colour inclines to scarlet this will be tinged with yellow; if very crimson it will be tinged with blue.

Mr. Gladstone (N. 376, H. 469) is naturally puzzled by the application of the epithet rosy to olive oil, but the above explanation disposes of the difficulty. I have certainly heard my friends describe as "rosy" objects which to my eye would fairly match the pale yellow of oil.

Κυάνεος.

This is a word the explanation of which appears to be involved in much difficulty. It is said to mean the colour of a substance called *kuanos*, but what this substance was, or even what its colour was, appears open to much doubt.

The usual translation of the adjective, according to Liddell and Scott, is "dark blue" (whence the chemical term *cyanogen*), and there is no doubt that, in later Greek, it acquired significations positively identified with this colour. Mr. Gladstone, in 1858 (H. 496), discussed the meaning of *kuanos* at much length, and thought it most probably referred to a native blue carbonate of copper, an interpretation in accordance with its subsequent use and description as a colour. If, therefore, this meaning were adopted, the word *kuaneos*, conveying a distinct idea of blue, could not be included in the same group with *xanthos*, *eruthros*, and *phoinix*, which all, as we have seen, belong to the opposite sensation.

But Mr. Gladstone, after reconsideration, appears, in his later article (N. 378, &c.), to have altered his view. He now considers it "almost certain that *kuanos* is bronze," and *kuaneos*, either "made of, or in hue like bronze." This implies the abandonment of the idea of blue as connected with the adjective; for, so far as I know, there is not a vestige of the blue element in the colour of any combination of copper and tin. In any case, however, there is no doubt that a very dark hue is referred to.

Now the impression conveyed by bronze to the colour-blind eye is very dark, almost black, but with a tinge of dark yellow-brown; and keeping this in mind, if we

review the various applications of the word given by Mr. Gladstone (N. 378, H. 462), we shall find nothing inconsistent with this explanation. It is applied—

To eyebrows, to hair, and to the coat of a horse, in any of which cases a very dark brown may be shown.

To a dark cloud, which may be of the same hue.

To the serried mass of the Greek and Trojan armies. "The colour of these," says Mr. Gladstone, "must have been derived from their arms, and these would probably be composed in the main of two elements, firstly copper, which is ruddy, and secondly, the hides of oxen upon the shields and elsewhere." He notes that to a normal eye the colours of these are not easy to combine in a common idea:—but to the colour-blind the combination is homogeneous enough; they both look dark yellow-brown, and the appearance is quite in accordance with the interpretation of the word *kuaneos* according to Mr. Gladstone's later view. When in 1858 he appeared generally to favour the blue interpretation he remarked justly that it could not hold in this instance.

To a very black mourning garment. But the blackest dyes have almost always some leaning either to brown or blue, and the use of another word instead of *melas* might possibly imply this leaning, without diminishing the intensity of the shade.

To the sea-sand, just left bare by the water, also yellow-brown. Here again the idea of blue seems inapplicable.

To Amphitrite, or the sea beating on rocks. The *deep* sea is dark blue or dark green; but its appearance close to the shore in shallow places may be so indefinite, that no positive inference can be drawn from this use of the term.

To the prow of a ship; this, we know by other passages, was painted with red earth or ochre, and if dark would appear the colour here implied.

We have here exhausted Mr. Gladstone's list of instances where this difficult word is used clearly as a colour-epithet. They are all perfectly consistent on the colour-blind hypothesis, clearly pointing to the classification of *kuaneos* in the yellow group; for, so far as I can judge, there is not a single instance where its application *necessarily* implies the idea of blue.

Mr. Gladstone remarks (H. 465):—

"The uses of this group of words (*i.e.*, the group formed from *kuanos*) thus appear to exhibit a degree of indefiniteness hardly reconcileable with the supposition that Homer possessed accurate ideas of colour; there is no one colour that can cover them all." This is true; but only suppose him dichromically colour-blind, and the dark yellow-brown hue he may call *kuaneos* will cover every example where he has used the term.

Χλωρός.

I suppose no doubt is entertained that this word, derived from *chloē* (young herbage), means, and always has meant, green, one of the most plentiful colours in nature, and one of the most positive and distinct to persons with ordinary eyes.

Now Homer's use of the word affords one of the strongest arguments as to the identity of his sensations with those of the colour-blind. Let us see the testimony which Mr. Gladstone offers to this fact. After quoting (H. 467) the application of the word to a pale face, to fresh-pulled twigs, to honey, to an olive-wood club, and to the nightingale, he remarks:—

"Upon the whole, then, *chlōros* indicates rather the absence than the presence of definite colour. If regarded as an epithet of colour it involves at once a hopeless contradiction between the colour of honey on the one side and greenness on the other. Again, the more we assume it to mean green the more startling it becomes that it could have taken paleness, as is manifestly the case, for its governing idea. . . . . The idea of green we scarcely find, unless once, connected with this word in the poems of Homer; and yet it is a remarkable fact that there is no other word in the poems that can even be supposed to represent a colour, which not the rainbow only, but every-day nature, presents so largely to the eye."

Again, in the later article Mr. Gladstone says (N. 380; the italics are mine):—

"It is plain, from the applications of it, that green was not on the list of Homer's colours. If I am to choose an English equivalent for the phrase it will be pale; and pale is not properly an epithet of colour so much as of light, although *there may perhaps be detected in it a very faint inkling*, so to speak, *of yellow*. If we strive to give the sense of colour we find there is none that will cover them in common, *yellow suiting in some cases*, green in others, neither of the two in all."

Speaking further of the application of *chloreïs* to the nightingale, he adds:—

"The balance of authority attaches the phrase to the hue or aspect of the bird, and, when so attached, it loses all definite idea of colour. . . . . Evidently enough, Homer's idea in this matter could not but be most vague and dim."

I have quoted these passages in order to show what a remarkably apposite commentary they offer on my own words, written twenty years ago.

"Green is a colour most perplexing to the patient, who cannot be said to manifest any definite sensation about it at all." It would scarcely be possible to give a more appropriate description than Mr. Gladstone has given of the impressions of the colour-blind in regard to green, although in all probability he knew little or nothing of these when he wrote the passages in question.

I have already explained how this arises, theoretically, from the invisibility of green proper to the colour-blind, and the appearance of green objects to them under false colours. As a matter of practice I have felt, throughout my life, that this colour has been my greatest stumbling-block, in regard to which my ideas and expressions have gone most astray.

In order to guess how a colour-blind person would be likely to use the term, we must bear in mind the fact, already stated, that the majority of greens in nature appear to him as varieties of yellow; chlorine gas, for example, which takes its name from the Greek word, is a decided yellow to me. And further, it is a fact within my own experience that, unless very powerfully coloured, such yellow greens have mostly a pale, washed-out appearance; indeed, if I find that a new object presents to my eye a sickly pale tint of yellow, I often make a successful chance shot in calling it green.

Keeping these explanations in mind, Homer's applications of the word appear quite natural.

The idea of paleness I have, I think, sufficiently explained. A pale face appears to me just such a sickly yellow as I have described.

I do not exactly know what the "fresh twigs" pulled by Eumæus to make a bed for Ulysses would be like, but they would probably be either green or brown, both which present to the colour-blind shades of yellow.

Honey, a pale yellow, is a perfect match to my eye with varieties of yellow green.

The club of the cyclops would be the colour of the bark of the olive tree, which is, I believe, a brownish grey, and would still be in the dark yellow category to the colour-blind.

The application of the term to the nightingale will naturally puzzle the normal-eyed, as the bird has nothing green about him. But he is described (N. 381) as a compound of tawny, olive, brown, and ash colour; and all these, except the last, which I do not quite understand, convey to the colour-blind the impression of modified yellow, by which chiefly they know green.

Οἶνοψ.

Wine-coloured. Homer (N. 377, H. 472), in speaking of wine, uses (omitting *aithops*, which, Mr. Gladstone thinks, may refer more to sparkling than to colour) two epithets: *eruthros*, red; and *melas*, black. This is con-

sistent enough with ordinary usage, as the red wine in the south of Europe often is very dark, and is called *vino nero*.

To the colour-blind, if red wine is moderately coloured it appears a dark yellow-brown, but when very dark the yellow element may disappear, being overpowered by the blue in the purple, when the impression is simply black, as to the normal-eyed. I frequently see strong red wines in which I can distinguish no colour at all.

Homer uses the word *oinops* for oxen, which, if a dark ruddy brown, would present to the colour-blind the same hue as red wine.

He also uses it for the sea, under special associations which seem to indicate darkness, as, for example, "under a rattling breeze at night." In such a case the sea would show no colour, and the term might be merely a poetical simile drawn from the *vino nero*.

We now come to the opposite group of colour-epithets, applied to objects which give to the colour-blind a sensation of blue; this group, in accordance with the comparative rarity of the impression it denotes, comprehends a less variety of words, being limited to two.

The most important is

Πορφύρεος,

which, I suppose, may be translated purple.

This word, with its compounds, has, Mr. Gladstone says, the largest and most varied application in Homer; he considers its use peculiarly embarrassing, and dwells (N. 373-4, H. 461) at considerable length on the anomalies it presents.

He states that Homer's uses of the word imply three very different forms of colour, namely, red, purple, and grey, and no doubt, to the normal-eyed, these are incongruous enough; but, when we consider the terms under the colour-blind aspect, the incongruities disappear.

The second colour appreciable to the dichromic vision is *blue*, and a great number of different hues in nature, which happen to contain blue in their composition, appear to the colour-blind as varieties or shades of this colour. For example, many crimson hues of red, verging towards violet, contain blue, and, being darkened by the red, show dark shades of this colour. Purple or violet is a still bluer compound. All blue-greens appear blue, and, in regard to dark greys, they often have blue in them, or at least give a blue impression.

Now assuming the poet to have dichromic vision, I suppose *porphureos* would be the most likely word in Mr. Gladstone's list to represent his idea of the various shades of blue; and it is easy to recognise its applications in this way by the examples given (N. 373, H. 461). Omitting the metaphorical uses of the word, we find it applied:—

To various articles of clothing and furniture, which might be of many colours, all conveying the sensation of blue.

To the rainbow. I have, in my paper, fully explained the appearance of the solar spectrum; it presents two colours only, the less refrangible part appearing yellow, the more refrangible part appearing blue. Hence a colour-blind person in speaking of the rainbow may correctly use either term. Homer appears to use both, for in another place he compares the rainbow to a dragon or a serpent, for which he uses the words *daphoinos* or *kuaneos*, both, as we have seen, belonging to the yellow category.

To blood. Under the word *eruthros* it has been pointed out that blood, when venous, loses what yellow element it possessed and by tending towards purple shows a blue impression to the colour-blind. This will account for the mention of blood in this class.

To a dark cloud. The prevailing hue of dark clouds is, both to the normal-eyed and the colour-blind, grey. But this grey may, by atmospheric causes, become tinged either with brown or with blue; the former case has been noticed under the word *kuaneos*, the latter comes in here.

To waves and to the darkening sea. The beautiful blue colour often seen in the Mediterranean is notorious, and to me, at least, it has been particularly marked in the darker aspects of the water.

To death. So far as this application of the colour epithet may be literal, it may be explained by the fact that the livid hue of a corpse has to the colour-blind a decidedly blue tinge.

Ἰοειδής.

Violet-coloured. This epithet clearly belongs to the blue group, for the colour violet is a compound of blue with red, and to the colour-blind eye the blue element alone is visible, the red addition having merely the effect of giving a dark shade. Hence the word may be used by them consistently enough for all impressions of darkened blue.

It is applied by Homer:—

To the sea, for which, on the colour-blind view, it is equally appropriate with *porphureos*.

To iron, which is both to the normal-eyed and to the colour-blind a bluish grey.

To wool, which Mr. Gladstone (N. 380) thinks may have been dyed to a deep purple.

To living sheep (H. 471). This application is not so intelligible, as, so far as I recollect the appearance of black sheep, their colour has inclined rather to brown than to blue. The word, however, used here is a compound one, *iodnephes*, meaning, according to Liddell and Scott, "violet-dark," and it may possibly refer to that variety of dark violet I have before mentioned, in which the blue tinge is indistinguishable. There would seem to be a certain analogy here with the use of *oinops* for the black sea.

Mr. Gladstone includes among his adjectives one which I call neutral, *i.e.*, used for objects which do not convey to the colour-blind either of their two colour sensations. This is

Πολιός,

usually translated grey or hoary. Mr. Gladstone says (N. 381, H. 466) it is applied to the human hair in old age, to iron, and to the hide of a wolf, in all which cases grey is a fair interpretation.

But it is also a stock adjective for the sea, being used for it in no less than twenty-four places. Now the standard colour of the sea (the blue being exceptional) is, I am told, green, and I know by my own observation that the particular hue of green is just that which is neutral to the colour-blind, thus appearing grey. It is possible that the word, in the sense of "hoary," may refer to the sea foam; but if it is really intended to mean grey, its repeated use for the green sea is an additional proof of the correspondence of the sensations of the writer with those of the colour-blind.

I pass over the words *aithos*, *aithops*, &c., as Mr. Gladstone, while finding great difficulty in their interpretation, hardly considers them epithets of colour.

It may be useful to add a summary, appreciable at a glance, of the various objects to which colour epithets have been applied by Homer, classifying them as above described.

GROUP I.—*Objects conveying to the Colour-blind the Sensation of Yellow or Yellow Darkened.*

Ξανθός—	Human hair.
	Coats of horses.
Ἐρυθρός—	Copper.
	Wine, Nectar.
	Blood (arterial).

Φοίνιξ—	Blood (arterial).
	Coat of a horse.
	The dragon or serpent.
	The rainbow.
	The jackal.
	The lion.
	Cloaks or mantles.
	Red prows of ships.
	The palm tree.
Ῥοδόεις—	The rose.
	Olive oil.
Κυάνεος—	Bronze.
	Dark eyebrows and hair.
	A dark cloud.
	The dark coat of a horse.
	Masses of armed men.
	Black mourning garments.
	Sea sand.
	The sea beating on rocks.
	Red prows of ships.
	The dragon or serpent.
Χλωρός—	A pale face.
	Fresh pulled twigs.
	Honey.
	Olive wood bark.
	The nightingale.
Οἶνοψ—	Red wine.
	Oxen.
	[The sea in circumstances of darkness.]

GROUP II.—*Objects conveying to the Colour-blind the Sensation of Blue, or Blue Darkened.*

Πορφύρεος—	Various articles of clothing and furniture.
	The rainbow.
	Blood (venous).
	A dark cloud.
	Waves and the darkening sea.
	Death.
Ἰοειδής—	The violet.
	The sea.
	Iron.
	Dark dyed wool.
	[Dark living sheep].

EXTRA GROUP.—*Objects conveying to the Colour-blind a Neutral Sensation.*

Πολιός—	Human hair in old age.
	Iron.
	The hide of a wolf.
	The sea.

I think the following propositions may be now taken as made out on the evidence supplied by Mr. Gladstone:—

1. That Homer's applications of colour epithets are in many cases inconsistent with the normal ideas in regard to them. This is the first and most general symptom of colour-blindness.

2. That this inconsistency is particularly noticeable in the use of the expressions for red and green. This is a further and more definite symptom, showing the peculiarly defective sensations in regard to these particular colours.

3. But that when the objects referred to are classified in two groups, according to the two colour sensations they respectively offer to the colour-blind eye, the use of the colour-epithets becomes consistent, no epithet belonging to one group being used (except in one doubtful case) for an object belonging to the other. This is a still more definite symptom, pointing, as it seems to me, to the *dichromic* nature of the malady.

It is not my province to carry the matter further; but if the explanation offered be correct, it may involve some very interesting considerations.

One may ask whether the defect in vision which gave rise to these singular uses of the colour epithets was likely to have been general among the people of the time? Do the expressions convey what would have been the general sense of the Greeks of the Homeric age? If so, we may fully concur in Mr. Gladstone's hypothesis, that the organ of colour was but partially developed among them, while at the same time we learn exactly what was the nature of their deficiency. It would be a most interesting fact in physiology and optics if we could show, in this way, that dichromatism was an early stage of human vision, out of which the present more comprehensive and perfect faculty has been gradually developed in the course of some thousands of years.

But on the other hand, it is quite possible that this defect was not general, that it existed only in the person or the writer whose language exhibits it. If this view is correct it may have a most important bearing on a dispute that has long agitated the scholarly world, namely, as to the authorship of the Homeric Poems.

If we can trace, running through the whole of these immortal works, the distinct and consistent evidence of a well-marked personal peculiarity in the writer—a positive characteristic by which his individual identity may be, in all parts, clearly inferred—we have the strongest possible proof, by internal evidence, of the existence of a single author, to whom the whole of the poems are due.

WILLIAM POLE

NOTES

AMONG the well-deserved decorations awarded in connection with the Paris Exhibition is that of Grand Officer of the Legion of Honour to the eminent chemist M. Pasteur.

AT the annual meeting of the Mathematical Society, November 14, Lord Rayleigh, F.R.S., instead of giving an address, will read a paper on the Instability of Jets.

IN connection with the operations of the United States Fish Commission during the past summer, *Harper's Weekly* furnishes some particulars of what may be considered as one of the most important discoveries of recent date in regard to the geology of North America. During the operations of the Commission a formation was met with which belongs probably to the miocene or later tertiary, as shown by the occurrence of numerous fragments of eroded, hard, compact, calcareous sandstone and sandy limestone. These are usually perforated by the burrows of *Saxicava rugosa*, and contain in more or less abundance fossil shells and fragments of lignite, radiates, &c. These fragments have generally been hauled up by trawl lines from depths of from 50 to 250 fathoms, and have already furnished a large number of species, some of them northern forms still living on the New England coast, others for the most part extinct. A conspicuous fossil of an undescribed species belongs to the genus *Isocardia*. Other genera are *Mya*, *Ensatella*, *Cyprina*, *Natica*, *Cardium*, *Cyclocardia*, *Fusus*, *Latirus*, *Turritella*, &c. The specimens so far obtained range from George's Bank to Banquereau, a region of at least several hundred miles in length, and extending along the outer banks from off Newfoundland nearly to Cape Cod. Indeed, it is suggested by Prof. Verrill that the formation constitutes in large part the plateaus known as fishing banks, frequented by such large numbers of cod, halibut, &c. The credit of bringing these specimens to light is due chiefly to Mr. Warren Upham, who originally visited Gloucester for the purpose of investigating certain glacial drift and fossiliferous deposits, and who obtained many of the specimens from fishermen who had brought them in and kept them as curiosities.

IN the summer of 1877 an expedition in the interest of the Princeton (U.S.) College Museum of Geology and Archæology was fitted out for the purpose of making explorations in

the tertiary beds around Fort Bridger and in Central Colorado, especially with a view of securing specimens of some of the interesting fossil vertebrates of which Prof. Cope and Prof. Marsh have described so many species. Six persons connected with Princeton College either as professors or students constituted the party, and the results of their labours were rich and varied beyond their expectation. The objects obtained since the return of the expedition have been subjected to a critical investigation by experts, and No. 1 of the report has just made its appearance in the form of a pamphlet of about 150 pages, with numerous illustrations. As might have been expected, the greater part of the collection consisted of species already collected and for the most part described. But in addition to these a considerable number of novelties rewarded the zeal of the explorers. These are described and many of them figured in the pamphlet referred to. Not the least valuable part of the report, *Harper's Weekly* states, consists of a systematic catalogue of the eocene vertebrates of Wyoming, as compiled from all accessible sources. Of the genera mentioned there are 70 belonging to the mammals, 3 to the birds, 27 to the reptiles and amphibians, and 17 to the fishes. Of species there are 114 of mammals, 7 of birds, 79 of reptiles and amphibians, and 51 of fishes, making a total of 251 species—certainly a very satisfactory showing for a portion of the extinct vertebrate fauna of the west.

As has been reported in the papers, M. Giffard's captive balloon has been sold to Mr. Gooch, of the Princess's Theatre, to be exhibited in London. The sale does not include the winding-up apparatus and machinery, which will remain in the Tuileries grounds, and be utilised for a second captive balloon, which will be built by M. Giffard, during the winter, for next season. The new captive balloon is to be enlarged and improved in details, so that its working capacities may be increased. The increased interest in ballooning has been manifested by the acceptance by the public authorities of the services of the École des Aéronautes Français for executing scientific ascents at Versailles on the day of the great *fête*, and at Paris on the occasion of the inauguration of the Mansion-house of the 19th arrondissement. This École des Aéronautes was established three years ago by a number of persons who escaped from Paris in a balloon during the siege, for the purpose of promoting practice in aeronautics.

NOTHING has occurred at the meeting of the Social Science Congress calling for special notice on our part. Lord Norton, the president, on the basis of doubtful statistics, seemed to think that the teaching of a "jumble of botany, physiology, &c.," in our elementary schools, is the cause of a supposed imperfection in the teaching of other branches in these schools. Certainly, if these subjects are jumbled they will do more harm than good, but as Lord Norton thinks our existing old universities are pretty near perfection, and are sufficient for the wants of the country, it may be doubted whether he has anything like an adequate knowledge of our educational needs. The Hon. G. C. Broderick seems to be pretty much of Lord Norton's opinion with regard to our universities, and virtually admitted that their highest purpose was to be "finishing schools for young gentlemen." On the question of increasing the number of our universities, there were various shades of opinion; all whose opinions are of any weight, however, agreed that increase is necessary, differing only as to the particular form which it should take.

THE following statement with regard to Mr. Edison's recent invention appears in the *Times*:—It appears, from the New York papers, that a company has been started in New York called "The Edison Electric Light Company," with a capital of 300,000 dollars. The object of the company is stated generally to be "the production of heat, light, and power by electricity." The present object, however, is to supply a fund which is to assist Mr. Edison in carrying forward his experiments to a point where he shall give a positive demonstration of the powers of his new inventions. Precisely what these inventions are in all their details of transmission of force and the multiplication of the light derived from electricity, Mr. Edison has not yet told to anybody, fearing that the devices may be patented abroad. The invention, as to the use of electric lights, it is said, will not include the use of carbon points, as ordinarily known in electric lights, but instead the incandescence of a metal simpler and cheaper in every way. Mr. Edison has determined upon the general features of his light, its manner of production, &c.; but in many minor points connected with the distribution of the light for ordinary domestic and business purposes much work has yet to be done. It was at first supposed that 100,000 dollars would be a sufficient experimental fund, but the larger amount was finally determined upon.

THE following is the title of the essay to which the Howard medal of the Statistical Society will be awarded in November, 1879; the essays to be sent in on or before June 30, 1879:—"On the Improvements that have taken place in the Education of Children and Young Persons during the Eighteenth and Nineteenth Centuries." The council have decided to grant the sum of 20*l.* to the writer who may gain the "Howard Medal" in November, 1879.

IN his just published report on the trade, &c., of Kiel, her Majesty's Vice-Consul states that the existence of a large bed of pure salt in the neighbourhood of Segeburg, about thirty-five miles distant, is certain. The bed lies about 144 metres from the surface. Two shafts were sunk, one of which reached 116 metres and the other 85 metres, when underground water filled both up to within 28 metres of the surface. Powerful pumps have been erected, which have emptied the water down to 40 metres, and, although constant pumping shows only a slight decrease, the chief engineer has no doubt of eventual success. In five days the largest pump brought up about 50,000 cubic metres of water, representing a weight of 50,000,000 kilos. The water contains from sixteen to twenty per cent. of salt. The report further states that, in the neighbourhood of Elmshorn, the German authorities are boring for coal. They have reached about 4,000 feet from the surface, but at present have found only red clay, intermixed with particles of salt.

ACCORDING to a Japan contemporary, an attempt, on a more extended scale than that of last year, has been made this season to introduce Japanese black teas into the European market. The samples sent in 1877 were favourably reported on, and it was hoped that an outlet had been found for the continually-increasing quantity of tea produced. These hopes, however, appear to be fading, and even if the existing prejudice against the article can be overcome, our contemporary finds it difficult to see how, with a yearly-increasing export from China and India, leaving Ceylon entirely out of the question, it can ever be made a paying speculation. Much is still hoped from the United States, but the verdict of the American trade upon it has yet to be received. From the same source we learn that the four Japanese gentlemen who were recently in Sydney have gone to Melbourne with the object of furthering an extension of trade with Australia, more especially in the direction of wool and sheep.

THE publication is announced (Ch. Stahl's Verlag in Neu-Ulm) of a "Grosses illustrirtes Kräuterbuch," containing a complete description of all plants and herbs in reference to their uses, their effects and application, their culture, collection, and preservation. It contains instructions for the preparation of all kinds of medicines, juices, syrups, conserves, essences,

powders, &c. The work contains coloured illustrations, and is published in fifteen parts.

ON Saturday evening a most interesting *soirée* took place at the Continental Hotel, Paris. The former pupils of the Central School of Arts and Manufactures received the foreign engineers who had taken part in the Universal Exhibition. At supper M. Dumas was in the chair, and had on his right hand M. Teisserenc de Bort, and on his left Mr. Cunliffe Owen. The hotel was illuminated as usual on such occasions, with the Jablochkoff candles, and a display of electric machines took place. While speaking of the exhibition we may state that the society for delivering lectures to the visitors, to the foundation and progress of which we have several times referred, has been a great success. It has been most heartily patronised by M. Bardoux, the Minister of Public Instruction. The visits to the exhibition by the working men travelling with the funds of the great lottery have been taken advantage of by the lecturing organisation, to give numerous special lectures in connection with the various industries. Not less than forty-four lectures were delivered on Monday week to as many different assemblies selected for the purpose.

A SILVER medal has been awarded at the Paris Exhibition to Mr. Edward Whymper for the engravings which he contributed. This is the highest award made to any British engraver, and is we believe the only silver medal that has been given to any engraver on wood of any country.

A CORRESPONDENT, Mr. Crowther, proposes that instead of using magneto-electric currents in the Bell telephone, induced electric currents be employed. This he proposes to accomplish by using adjacent flat spirals of copper wire, through one of which a current is sent and the other joined to the line wire and attached to a similar receiver at the distant end. We believe a somewhat similar suggestion has already been tried but with no practical benefit.

IT is stated that in the Island of St. Vincent the cocoa-nut palm (*Cocos nucifera*) is now found very sparingly, though at one time the palm was one of the most profitable of all the plants grown in the island. About a quarter of a century ago the palms were visited by a severe blight, from which they have never recovered. It is calculated that about a million cocoa-nut trees are about the present time bearing fruit in the archipelago of Seychelles, and during the next five years quite half as many more will probably be producing fruit.

HIGHLY interesting remains of Roman structures have recently been discovered on the Capersburg, near Friedberg, in the Grand Duchy of Hessen. The excavations are under the direction of Herr G. Dieffenbach, and are being made at the instigation of the Hessian Historical Society of Darmstadt.

THE Leeds Philosophical and Literary Society send us an attractive programme of lectures, mostly scientific, for session 1878-9. We notice that on January 7 Prof. Thorpe is to lecture on the Solar Eclipse of 1878.

SIGNOR A. PONTI, of Milan, has intimated to the Paris Academy that he intends to place at its disposal a sum of 60,000 lire for the foundation of an annual prize, to be distributed as the Academy thinks advisable.

IN Class 15 of the Paris Exhibition, a gold medal was awarded to Messrs. Légé and Co., not Léqé, as misspelt in the "first proof" of the list referred to last week.

ON September 23-26, 1879, the third meeting of the "International Congress of Americanists" will take place at Brussels, under the protectorate of the King of the Belgians and the presidency of the Count of Flanders.

WE have received Part I. of "The Herefordshire Pomona," containing coloured figures and descriptions of the most esteemed kinds of apples and pears, edited by Robert Hogg, LL.D., F.L.S., and published under the auspices of the Woolhope Club (London: Hardwicke and Bogue). The work promises to be one of the most magnificent of its kind, and the coloured illustrations are the finest specimens of chromolithography we have seen; they are by Severeyns, of Brussels. The text, besides descriptions of the various kinds of apples and pears figured, contains a learned and interesting paper by Dr. Bull "On the Early History of the Apple and Pear," and by the same author, a "Life of Thomas Andrew Knight," the eminent horticulturist, of whom there is a fine portrait. This work is in the highest degree creditable to the Woolhope Club. From a prefixed notice we learn that "The Herefordshire Pomona" was originally intended to form a work of local character, as its title indicates, but the great and widespread interest with which the announcement of its publication has been received induces the Woolhope Club to believe that it will be more useful if its scope be made more general. It is intended, therefore, subject to the favour and support it may meet with, to make this Pomona a thoroughly English work. Its local name will still be retained, but it will embrace all apples and pears of established merit cultivated in Great Britain, even though some of the new, or special varieties, may not as yet be grown in Herefordshire. The Second Part of "The Herefordshire Pomona" will be published during the summer of 1879, and will contain, in continuation of the introductory matter, a paper "On Modern Apple Lore;" "A Sketch of the Life of Lord Scudamore," by Dr. Bull, with a full-page portrait; and a paper "On the Cordon System of Growing Pears," by Sir Henry E. C. Scudamore Stanhope, Bart., with a full-page woodcut of the Cordon Wall at Holme Lacy. These will be followed by six coloured plates of such different varieties of fruits as may be procured in perfection during the ensuing season. The Pomona Committee of the Woolhope Club will feel indebted for any assistance that may be rendered to them by supplying information with reference to any new or rare apples and pears of acknowledged merit; their origin, date of production, and description of the fruit. If it be desired to submit them to the judgment of the Committee, with a view to their publication in the work, it will be necessary to send a few well-grown typical specimens of the fruit, that such as are selected may be carefully drawn and coloured from nature, and their descriptions and merits verified. Parcels of fruit should be sent to "The Pomona Committee, Free Library, Hereford."

A NEW mineral spring has recently been discovered at Suhl, in Thuringia, which is particularly rich in chloride of calcium, according to the analysis of Professors Reichardt (Jena) and Sonnenschein (Berlin). Otherwise it resembles the Elizabeth spring of Kreuznach in its composition. The authorities of Suhl intend transforming their charmingly situated little Thuringian town into a fashionable watering-place.

THE twenty-fifth volume of the excellent German scientific series, *Die Naturkräfte*, contains an able treatise on the conservation of energy as the basis of modern physics, by Dr. G. Krebs, of Frankfort-on-the-Main. After some introductory chapters on the changes occurring in nature, on forces, the conversion of finite motions and the meaning of the words work and energy, the author gives a condensed explanation of the sound-oscillations, the conversion of kinetic into caloric energy, and the mechanical equivalent of heat. He then treats of the inner constitution and the three aggregate states of matter, the propagation of heat and light, the identity of the last-named forces, and ends with a chapter on electricity and magnetism, and one on the dispersion of energy. The little book contains numerous woodcuts.

THE additions to the Zoological Society's Gardens during the past week include two Macaque Monkeys (*Macacus cynomolgus*) from India, presented respectively by Capt. E. Waterhouse and Mr. Samuel Thomson; a Common Roe (*Capreolus caprea*) from Greece, presented by Mr. Edward Jones; a Common Jackal (*Canis aureus*) from India, presented by Capt. Easson; a Common Seal (*Phoca vitulina*), European, presented by Messrs. Thompson and Gough; a Bornean Fireback (*Euplocamus nobilis*) from Borneo, presented by Mr. A. Dent; two Mandarin Ducks (*Aix galericulata*) from China, presented by Mr. Edward Trelawny; a Common Marmoset (*Hapala jacchus*), a Tuberculated Lizard (*Iguana tuberculata*), a Teguexin Lizard (*Teius teguexin*), a Merrem's Snake (*Liophis merremi*), a Black-headed Snake (*Homalocranion melanocephalum*), a Plumbeous Snake (*Oxyrhopus plumbeus*), a d'Orbigny's Snake (*Heterdon d'orbignyi*), an Anaconda (*Eunectes murinus*) from South America, purchased; a Collared Fruit Bat (*Cynonycteris collaris*), born in the Gardens.

A NEW GALVANOMETER FOR STRONG CURRENTS

ON the following principle an ordinary tangent galvanometer can be transformed into an instrument suitable for the measurement of strong currents such as produced by powerful magneto- or dynamo-electric machines.

Suppose the circular coil of a tangent galvanometer mounted so as to turn round its horizontal diameter lying in the meridian, and assume the needle to be freely movable *in all directions*, then the effect which the current produces upon the magnet at different inclinations of the coil to the horizontal plane is as follows:—

1st. If the ring is in the vertical position (in the meridian) we have the ordinary form of tangent galvanometer, for which

$$\tan \alpha = \frac{k\,I}{H} \quad . \quad . \quad . \quad . \quad . \quad (1)$$

where α is the deflection of the needle in the horizontal plane, I the strength of the current, k a constant depending upon the dimensions of the coil, and H the horizontal component of the earth's magnetism.

2nd. If the ring is in the vertical position the magnet is only deflected in the plane of the meridian, and the deflection is determined by

$$\tan \beta = \frac{k\,I}{V} \quad . \quad . \quad . \quad . \quad . \quad (2)$$

where β is the deflection and V the vertical component of the earth's magnetism. This would be a tangent galvanometer in which the directive force of the current is opposed by the *vertical* component of the terrestrial magnetism.

By the combination of these two formulæ we obtain

$$\frac{\tan \alpha}{\tan \beta} = \frac{V}{H}.$$

Hence, the tangents of the two deflections are in inverse proportion respectively to the two components of the earth's magnetism.

Since $\frac{V}{H} = \tan i$, where i is the "magnetic dip," this relation may be used to ascertain the "dip" by a method similar to that of Prof. Wilhelm Weber by the inductive action of the earth.

3rd. If the ring is neither in the vertical nor in the horizontal position, but is inclined at any angle ϕ to the horizontal plane, the magnet is simultaneously deflected from the plane of the meridian through an angle α and from the horizontal plane through an angle β. In this case we have to introduce, instead of k in the equations 1 and 2 respectively, $k \sin \phi$ and $k \cos \phi$, whereby they become

$$\tan \alpha = \frac{k\,I}{H} \cdot \sin \phi \quad . \quad . \quad . \quad . \quad . \quad (3)$$

$$\tan \beta = \frac{k\,I}{V} \cdot \cos \phi \quad . \quad . \quad . \quad . \quad . \quad (4)$$

Combining these two equations we obtain the formula

$$\frac{\tan \alpha}{\tan \beta} \cot \phi = \frac{V}{H} = \tan i,$$

ϕ being known and α and β read off, the "dip" may be found by such measurements without *altering* the inclination of the coil.

If the ring is gradually brought from the vertical to the horizontal position, whilst a current I passes through it, the deflection α decreases proportionally from the maximum $\tan \alpha = \frac{k\,I}{H}$ to zero. At the same time the deflection β increases from zero to the maximum $\tan \beta = \frac{k\,I}{V}$.

For practical measurements we need only consider the deflection α in the horizontal plane, and for this reason the needle should work on a vertical axle pivoted at both ends.

With this form of instrument I was enabled to measure very strong currents.

It will be readily understood that a current which would throw the needle to nearly 90° when the ring is vertical, will, when it is suitably inclined, only deflect the needle to that part of the scale (45°) where readings are most accurate.

If the instrument and place of observation remain the same, we can substitute in equation (3) a new constant K for $\frac{k}{H}$ whereby it is simplified to

$$\tan \alpha = K\,I \sin \phi.$$

Further we have for other currents I_1, I_2, &c., at other angles of inclination ϕ_1, ϕ_2, &c.

$$\tan \alpha_1 = K\,I_1 \sin \phi_1,$$
$$\tan \alpha_2 = K\,I_2 \sin \phi_2, \text{ \&c.,}$$

hence,

$$\tan \alpha : \tan \alpha_1 : \tan \alpha_2 \ldots = I \sin \phi : I_1 \sin \phi_1 : I_2 \sin \phi_2, \text{ \&c.,}$$

$$\text{or } I : I_1 : I_2 \ldots = \frac{\tan \alpha}{\sin \phi} : \frac{\tan \alpha_1}{\sin \phi_1} : \frac{\tan \alpha_2}{\sin \phi_2} \ldots$$

By this relation different currents measured at different inclinations of the ring can be compared.

The following separate cases may serve as further illustrations:—

Case 1. Currents of different strength I_1, I_1, $I_2 \ldots$, sent through the coil at the same inclination ϕ, give—

$$\tan \alpha : \tan \alpha_1 : \tan \alpha_2 \ldots = I : I_1 : I_2 \ldots$$

Therefore the law of tangents holds also for the inclined ring.

Case 2. The same current I sent through the ring at different angles of inclination ϕ, ϕ_1, $\phi_2 \ldots$ gives

$$\tan \alpha : \tan \alpha_1 : \tan \alpha_2 \ldots = \sin \phi : \sin \phi_1 : \sin \phi_2 \ldots$$

$$\text{or } \frac{\tan \alpha}{\sin \phi} : \frac{\tan \alpha_1}{\sin \phi_1} : \frac{\tan \alpha_2}{\sin \phi_2} = \ldots = C$$

where C a constant.

The tangents of the deflections are therefore in the same proportion as the sines of the inclinations; or in other words, the tangents of the deflections divided by the sines of the corresponding inclinations give for the same strength of current a constant value.

Case 3. For different currents I, I_1, $I_2 \ldots$ sent through the ring at inclinations ϕ, ϕ_1, $\phi_2 \ldots$ giving the *same* deflection α (say of 45°) we have

$$I : I_1 : I_2 : \ldots = \frac{1}{\sin \phi} : \frac{1}{\sin \phi_1} : \frac{1}{\sin \phi_2} \ldots$$
$$= \operatorname{cosec} \phi : \operatorname{cosec} \phi_1 : \operatorname{cosec} \phi_2 \ldots$$

and the instrument thus used acts as a *cosecant* galvanometer.

The instrument which I used to ascertain the degree of accuracy of the method described consisted of a wooden ring of 30 cm. diameter, wound for some experiments with a few convolutions of wire, and for other experiments with a copper band. This ring, in the centre of which a small magnetic needle was placed, could be turned round its horizontal diameter, and its inclination read off on a graduated quadrant. To adjust the instrument the ring is approximately placed in the horizontal position; a current is then sent through the coil, and if the needle is deflected from the meridian, the inclination of the ring must be carefully altered until no deflection occurs. In this position the quadrant is fixed so that its zero point coincides with the index attached to the coil, and the instrument is now ready for use.

The following tables contain records of some of the experiments made with this instrument:—

Table I. gives the results obtained with a coil of seven convolutions of wire of ·074 Siemens' units resistance, and with a needle turning on a point. One Bunsen's cell was used, and the strength of current varied by the introduction of resistances. For each current-strength readings were taken at inclinations of the ring, the sines of which are proportional to the even integers 2 to 10.

TABLE I.

Resistance in circuit.	1 S. U.			2 S. U.			3 S. U.			4 S. U.			5 S. U.			6 S. U.			1 S. U.		
sin φ	α	tan α	tan α / sin φ	α	tan α	tan α / sin φ	α	tan α	tan α / sin φ	α	tan α	tan α / sin φ	α	tan α	tan α / sin φ	α	tan α	tan α / sin φ	α	tan α	tan α / sin φ
1	59°·5	1·698	1·70	45°·9	1·032	1·03	35°·47	·7125	·712	28°·7	·5475	·547	23°·9	·4431	·443	20°·35	·3709	·371	61°·87	1·871	1·87
·8	56·2	1·494	1·87	39·5	·8243	1·03	29·7	·5704	·713	23·55	·4358	·545	19·42	·3526	·441	16·57	·2975	·372	56·32	1·500	1·87
·6	48·25	1·120	1·87	31·72	·6181	1·03	23·15	·4280	·713	18·0	·3249	·541	14·85	·2651	·442	12·4	·2199	·367	48·3	1·122	1·87
·4	36·67	·7446	1·86	22·17	·4061	1·01	15·85	·2839	·710	12·22	·2166	·541	10·0	·1763	·441	8·25	·1450	·362	36·87	·7450	1·86
·2	20·27	·3693	1·85	11·70	·2071	1·03	8·02	·1409	·704	6·05	·1060	·541	5·0	·0875	·437	4·17	·0729	·364	20·27	·3693	1·85

It will be seen from this table that the value of $\frac{\tan \alpha}{\sin \phi}$ is as nearly a constant as can be expected from this kind of measurement.

Table II. gives the results obtained with the same coil and needle as before, but with the current unaltered in strength (one Bunsen's cell suitably reduced by the insertion of a small resistance). The order of experiments is shown by the arrows.

TABLE II.

	I.			II.			III.		
sin φ	α	tan α	tan α / sin φ	α	tan α	tan α / sin φ	α	tan α	tan α / sin φ
·1	10°·4	·1835	1·83	10°·25	·1808	1·81	10°·25	·1808	1·81
·2	20·2	·3679	1·84	20·15	·3669	1·83	20·15	·3669	1·83
·3	29·1	·5566	1·85	29·05	·5554	1·85	29·00	·5543	1·85
·4	36·95	·7522	1·88	36·75	·7467	1·87	36·65	·7440	1·86
·5	42·95	·9309	1·86	42·85	·9276	1·85	42·95	·9309	1·86
·6	48·15	1·116	1·86	48·15	1·116	1·86	48·1	1·115	1·86
·7	52·45	1·301	1·86	52·5	1·303	1·86	52·45	1·301	1·86
·8	56·2	1·494	1·87	56·05	1·485	1·86	56·2	1·494	1·87
·9	59·1	1·671	1·86	59·1	1·671	1·86	59·1	1·671	1·86
1	61·9	1·873	1·87	61·8	1·865	1·86	61·7	1·857	1·86

The smaller value of the constant at the top of each column is doubtless due to slight mechanical inaccuracies in this *experimental* instrument.

Table III. gives the results obtained with the copper band provided with stout leading wires and with the needle fixed to an axle. The resistance of the copper band, including the leads, was only ·001 Siemens' units. Three Bunsen's cells connected parallel were used without additional resistance.

TABLE III.

sin φ	α	tan α	tan α / sin φ
1	66°·9	2·344	2·34
·8	61·6	1·849	2·31
·6	54·4	1·397	2·33
·5	49·4	1·167	2·33
·4	42·9	·9293	2·32
·2	25·1	·4684	2·34
·1	13·2	·2345	2·34
1	66·8	2·333	2·33

In this table the greatest difference from the mean of the constant (2·33) is not more than ·8 per cent.

The foregoing experiments having shown that the measurements with this instrument are, as to exactness, in no way inferior to those with the usual form of tangent galvanometer, I also employed it for the currents of dynamo-electric machines.

The first of these experiments was made with a Siemens' machine of smallest size. Besides the galvanometer an electric lamp was in circuit. The strength of the current and the intensity of the light was measured, and at the same time the number of revolutions of the armature counted. The results are given in the next table.

TABLE IV.

Revolutions of armature.	Deflection α (sin φ = ·2)	tan α	tan α / sin φ	Intensity of light in standard candles.
860	38°	·7813	3·906	3200
851	37	·7536	3·768	2750

The second experiment was made in the same way as the preceding, but with a Siemens' machine of medium size. The results are given in

TABLE V.

Revolutions of armature.	Deflection α (sin φ = ·1)	tan α	tan α / sin φ	Intensity of light in standard candles.
660	28°	·5317	5·317	4100
696	33·5	·6619	6·619	6400
692	33	·6494	6·494	7700[1]

The deflections in the experiments with the small machine were taken with the galvanometer ring at an inclination, the sine of which is equal to ·2; with the larger machine the sine of the angle of inclination was equal to ·1. The column headed $\frac{\tan \alpha}{\sin \phi}$ gives in both cases the tangent of the deflection which would be obtained with the vertical ring.

By these two tables I intend merely to show that even such powerful currents which give a light of thousands of candles produce readable deflections with a suitable inclination of the ring.

I may add that the method I have just described to reduce the action of a coil upon the magnetic needle by turning it round a horizontal axis will scarcely be limited to the tangent galvanometer, but that this method very likely can be used with other galvanometric apparatus for many purposes where shunts are not desirable.

EUGEN OBACH

GULF-WEED[2]

FROM the time of Columbus to the present day the gulf-weed growing in the "Sargasso Sea" has attracted the attention and excited the interest of all voyagers who have crossed the

[1] With other carbon points than used before.

[2] Om de under Korvetten *Josephines* expedition, sistliden sommar (1869), insamlade Algerne. Af J. G. Agardh, Öfversigt af *Kongl. Vetenskaps-Akademiens Förhandlingar*, 1870, No. 4, Stockholm.

Enumeration of Algæ collected by Mr. Moseley, Naturalist to H.M.S. *Challenger*, at St. Thomas, Bermudas, Coast of Brazil, Cape de Verde Islands, St. Paul's Rocks, Fernando de Noronha, Tristan d'Acunha, Inaccessible Island, Simon's Bay, Seal Island, Marion Island, Heard Island, and Kerguelen's Island. By Prof. G. Dickie, M.D., F.L.S., Linnean Society's *Journal*—Botany, vol. xiv.

Atlantic. Almost every one who meets with the plant on his first trip across the ocean brings home a small bottle filled with the weed, which is shown to admiring friends, and then put away and forgotten. But the plant is much too interesting to be thus thrown aside without examination. Let the bottle be carefully broken so that the gulf-weed may be removed without injury; then place it in salt water—in sea-water if it can be got—in a large vessel of clear glass, where it will have room to expand, and then will be seen its beauty and grace of form, no small addition to which are the pretty and minute species of Campanularia, Plumularia, and Sertularia which twine around its branches, while other parts of the plant are covered by Polyzoa with a delicate lace-work as hard as stone.

But it is not only on account of its beauty that gulf-weed is deserving of attention; there is a history attached to it which renders it one of the most interesting vegetable productions of the sea. I propose, therefore, to give a summary of all that is yet known respecting the habits and history of this plant.

Whether the Sargasso Sea was known to the ancients is doubtful. Two descriptions, by ancient writers, of a kind of "Mar de Sargasso," near the coast of Africa, have been transmitted to us.

Humboldt ("Aspects of Nature," pp. 46, 47, Bohn's edition) has shown that both these descriptions refer to localities too near the coast of Africa to be applicable to the Sargasso Sea. The first description is from a work which Humboldt says for a long time bore incorrectly the name of Aristotle; it is as follows:—"Phœnician mariners came in a four days' voyage from Gades to a place where the sea was found covered with rushes and sea-weed. The sea-weed is uncovered at ebb, and overflowed at flood tide." There are no rushes mixed with the sea-weed in the Sargasso Sea, neither is the weed covered or uncovered by the water according to the state of the tide. The second description, from the Periplus, which has been ascribed to Scylax, of Caryanda, is thus quoted by Humboldt: "The sea beyond Cerne [1] ceases to be navigable in consequence of its great shallowness, its muddiness, and its sea-grass. The sea-grass lies a span thick, and it is pointed at its upper extremity, so that it pricks." Now the Sargasso bank is in deep water, which is not muddy, and no sea-grass (which inhabits shallow water) ever grows on it. The Sargasso bank is much more than a span in thickness, and the upper extremity of the plant is not sharp enough to prick.

Columbus and his followers called the floating sea-weed "sargazo," a term which botanists have modified into SARGASSUM, as the generic name, adding, as the specific name, *bacciferum*, alluding to the great number of berry-like air-vesicles which assist to buoy up the plant when in the water. This alga is also sometimes called "*Fucus natans*," on account of its being found floating on the sea, and not attached to the shore or to rocks, while to sailors it is known by the name of "gulf-weed," and that part of the sea where it is met with in greatest abundance is called the Sargasso Sea.

The Sargasso Sea is situated in the North Atlantic, between 22° and 36° N. latitude, in the comparatively quiet space which is bounded on the south by the great Equatorial current, on the west and north by the Gulf Stream, and on the east by the Guinea current, which flows southwards. Humboldt [2] states that there are two principal banks, the larger of which lies a little to the west of Fayal, one of the Azores; the smaller near to the Bahamas. The situation, however, of the weed-banks varies in different seasons, according to the prevalent winds. Maury states [3] that "an area equal in extent to the Mississippi Valley, is so thickly matted over with gulf-weed, that the speed of vessels passing through it is often much retarded. When the companions of Columbus saw it, they thought it marked the limits of navigation, and became alarmed. To the eye, at a little distance, it seems substantial enough to walk upon. Patches of the weed are generally to be seen floating along the outer edge of the Gulf Stream. The sea-weed always 'tails' to a steady or constant wind, so that it serves the mariner as a sort of marine anemometer, telling him whether the wind, as he finds it, has been blowing for some time, or whether it has just shifted, and which way. Columbus first found this weedy sea on his voyage of discovery; there it has remained to this day, moving up and down, and changing its position, like the calms of Cancer, according to the seasons, the storms, and the winds. Exact observation as to its limits and their range, extending back for fifty years, assure us that its mean position has not been altered since that time." Dr. Harvey says [1] that he had made the voyage across the Atlantic four times, and only once found gulf-weed in any quantity. It then occurred in ridges of great length from ten to twenty yards in breadth. These ridges are separated by water, which flows between them like rivers or lakes.[2]

One fact respecting the gulf-weed, hitherto unnoticed by botanists, has not escaped the keen eye of the sailor, namely, that the plants rise a few inches *above* the water, the upper branches not being immersed; hence it is readily observed from a distance. It is this power of supporting the upper branches out of the water in an erect position—a very unusual power in sea-weeds—that enables the gulf-weed to "tail" to the wind, as before mentioned.

Another peculiarity attending the floating weed is that no other marine plant has ever been found growing on it or with it; small zoophytes and polyzoa are, however, often attached to it. Although its vegetation is limited to one species, the Sargasso Sea is a great resort of animal life, and it lies within the northern limits of the wanderings of the Sperm whale. The Right whale sometimes crosses its northern boundary, where the water is cooler.

A third peculiarity affecting the *floating* gulf-weed is that it has neither root nor fruit; never in the Atlantic, or in other localities where it is met with, has it ever been found in fruit. [3] On this point I shall have more to say hereafter.

The genus Sargassum is the most highly organised of the Melanospermeæ, or olive-coloured sea-weeds. It possesses root, stem, branches, leaves, air-vesicles, and distinct organs of fructification. The species are very numerous. Agardh, in his "Species, Genera et Ordines Algarum," part I, published in 1848, describes 126 species, which number has since been greatly increased. These species are classified into three sections and twelve tribes. Gulf-weed belongs to the highest section, namely, *Eu-sargassum*, or Sargassum proper, and to the twelfth tribe Cymosæ.

The genus Sargassum inhabits the tropical and sub-tropical seas of both hemispheres, extending on each side of the equator to about the 45° parallel of latitude, gradually increasing in number of species towards the line. With the exception of *S. bacciferum* (gulf-weed) and *S. vulgare*, which is also sometimes called "*Fucus natans*," [4] the species are very local. Thus some grow on the coasts of Australia only, and the species of North Australia differ from those of the south. A remarkable group of Sargasso inhabits the coasts of Japan, where the plants grow in the warm waters of "the Black Current," the Pacific analogue of the Gulf-Stream of the Atlantic; other species are found in the China Seas, many in the Indian Ocean, and these are generally distinct from those of the Red Sea. The section *Cymosæ*, to which Gulf-weed belongs, inhabit chiefly the Atlantic and Indian Oceans and the Australian coasts.

With these extremely local habits, and permanently distinct species, it seems difficult to reconcile the errant habits and the fixed forms of *S. vulgare*, and the plant which has given its name to the Sargasso Sea; both species are found in most of the warmer seas in both hemispheres.[5] Slight deviations sometimes occur in these plants, but they are clearly traceable to local causes. Thus, in the Sargasso Sea, the plants have often shorter leaves, the branches are contracted, and the bristles of the air-vessels broken off; whereas, specimens from Sydney, New South Wales, have longer leaves, the air-vessels have very long bristles, which frequently form narrow leaves, and the habit of the plants is more lax and straggling.

S. vulgare produces fruit in all the localities where it is found; but, with regard to *S. bacciferum*, it has already been

[1] "The Phœnician station for merchant vessels (Gaulea); or, according to Gosselin, the small estuary of Fedallah, on the north-west coast of Mauritiania."—Humboldt. *Ib.*

[3] "Physical Geography of the Sea," p. 28, tenth edition.

[1] "Manual of British Algæ." Introduction, p. xxi., xxii., second edition.

[2] Besides the Sargasso-bank, in the Atlantic, Maury mentions several other accumulations of sea-weed known to mariners as "Sargassos." The immense banks of weeds in the South Pacific, through which ships pass in going to the Australian colonies, consist principally of a pelagic form of Macrocystis; of the composition of the other weed-banks little is known.

[3] "Om de under Korvetten *Josephines* expedition, sistlidensommar (1869) insamlade Algerne." Af J. G. Agardh, Öfversigt af *Kongl. Vetenskaps-Akademiens Förhandlingar*, 1870, No. 4, Stockholm.

[4] It is much to be regretted that this term "*Fucus natans*" should not have been limited by authors to *S. bacciforum*.

[5] *S. bacciferum* is found in the Atlantic, between 22° and 58°, being sometimes carried on the Gulf Stream as far as the Orkney Islands. It is also found on the coasts of Spain and Portugal, and in the Mediterranean Sea, its presence in these localities also being due to the Gulf Stream. It is likewise met with in the Indian Ocean, the Pacific, on the coasts of Australia, and New Zealand.

observed that the specimens found *floating* in all the seas are always barren. The question then arises, how is the floating weed propagated? To this question Dr. Harvey[1] replies:—"It seems to me that the old frond, which is exceedingly brittle, is broken by accident, and the branches, continuing to live, push out young shoots from all sides. Many minute pieces that I have examined were as vigorous as those of a large size; but they were certainly not seedlings, and appeared to me to be broken branches, all having a piece of the old frond from which the young shoots spring. As the plant increases in size it takes something of a globular form, from the branches issuing in all directions, as from a centre."[2] The specimens brought to this country are merely the uppermost branches, the whole plant often attaining a diameter of three or four feet. The upper branches are of a light olive colour, the lower more or less brown; the lowest parts of all wither and decay, and finally drop away.

With regard to the origin of the plant there has been much controversy among algologists. On this point Harvey observes:—[3] "Nothing has yet been discovered; for, though species of Sargassum abound along the shores of tropical countries, none exactly corresponds with *S. bacciferum*. That the ancestors of the present banks have migrated from some fixed station is probable, but further than probability we can say nothing." Prof. Agardh, however, thought he had found the parent stock in a plant which grows on the banks of Newfoundland; and in his "Species, Genera, et Ordines Algarum," vol. i., published in 1848—a year before the second edition of Harvey's "Manual" appeared—thus writes of it:—"Natans semper sterilis, nec in pratis Atlanticis fructigera, Fructiferam et affixam e mari Americanum alluente habeo." In his before-mentioned notes on the algæ collected by the *Josephine* expedition, after referring to the passage just quoted, he says:—"I have received from the banks in the neighbourhood of Newfoundland specimens with root and fruit, which, although somewhat different in form, I nevertheless did not scruple to consider as belonging to the same species" (*S. bacciferum*); and he adds that "from no facts yet come to my knowledge have I had reason to change the opinion I had expressed in 1840 at the meeting of naturalists at Copenhagen, that the floating form originates from the Banks of Newfoundland, and perhaps grows on similar localities on the east coast of America, when it is provided with root and fruit." Since the publication of these observations, additional information relative to the fruit of *S. bacciferum* has been obtained. Specimens "covered with fructification" have been found by Mr. Moseley,[4] the naturalist of the *Challenger* expedition, in Harrington Sound, Bermudas, which islands lie in the very heart of the Sargasso Sea.

The fact, therefore, that *S. bacciferum* bears fruit *when attached to the land* in the Sargasso Sea and the Gulf Stream, may be considered as established.

With regard to the comparative antiquity of the Bermudas and Newfoundland plants, it must be observed that they both occur within the influence of the Gulf Stream. It is not likely that the Sargassum could make its way from the northern locality *against* the current of the stream; hence it seems most probable that it vegetated first at Bermudas, and thence emigrated, with the stream, northwards.

Other facts in connection with the two islands favour this view. Sir Wyville Thomson says[5]:—"Bermudas is practically an 'atoll,' or annular coral reef. . . . . What the basis on which the Bermudas reef rests may be, we have no means of telling; in fact, its having the form of an atoll precludes the possibility of our doing so. There seems to be little doubt, from Darwin's beautiful generalisation, which has been fully indorsed by Dana and other competent observers, that the atoll form is due to the entire disappearance by subsidence of the island round which the reef was originally formed. The abruptness and isolation of this peak, which runs up to a solitary cone about equal to that of Mont Blanc, is certainly unusual; probably the most reasonable hypothesis may be that the kernel is a volcanic mountain comparable in character with Pico in the Azores or the Peak of Teneriffe." It has been also stated[1] that "in the process of excavations carried out in order to accommodate the great floating dock, a bed of peat, with stumps of cedar trees in a vertical position, was found at a depth of forty-five feet below low-water mark, covered by beds of rock. Most conclusive proof is thus afforded that the Bermudas have changed their level, and sunk since they have been covered with a similar vegetation to their present one." These statements afford considerable evidence of the antiquity of the Bermudas. Now as to the comparative age of the Newfoundland Banks. Lieut. Payer[2] has observed respecting them:—"It is an established fact that ice-bergs and ice-fields laden with the *débris* and rubbish of Arctic lands, deposit these burdens round the outer edge of the Frozen Ocean, and to this process, partially at least, the origin of the Newfoundland banks is to be ascribed." It would seem from these observations that these banks have been formed since the glacial period, hence that they are more recent than the Bermudas. On the above grounds, therefore, it is but reasonable to conclude that the Bermudas plant has superior claims to that of the Newfoundland banks to be considered as the parent-stock of the Atlantic plant.

That the parent-stock originated in the Atlantic, and then found its way into the Indian and Pacific Oceans is, at least, doubtful, especially as a form of the plant called var. Capillifolium,[3] bearing fruit abundantly, has been found at Mauritius by Col. Pike. Thus, then, in two oceans out of the three, *S. bacciferum* has been obtained in fruit, but with sufficient differences in the forms to constitute varieties; whether the Bermudas plant differs from the others I have not been able to ascertain.

Prof. Mertens (see his work on the algæ collected by the Prussian expedition to Eastern Asia) supposed that *Sarg. dentifolium*, of the Red Sea, was the parent-stock of the floating Sargassum, on the ground that the same species of polyzoa were found on both plants. Not a very strong argument, especially as a remarkable difference exists in the structure of the two plants. *S. dentifolium* has a serrated midrib, while that of *S. bacciferum* is plain. This difference was observed by Prof. Agardh, who, in addition, expressed his belief[4] that *S. dentifolium*, an inhabitant of a tropical sea, could not make, or survive, the voyage round the Cape of Good Hope. It must then have had other means of making the voyage, as the plant has actually been found at Key West, Florida, by Dr. E. Palmer. Dr. Farlow,[5] who mentions this fact, observes: "It is not stated whether it was floating or attached. Dr. Palmer's specimens are more luxurious than those of the Red Sea, but the serrated midrib seems sufficiently characteristic to warrant us in supposing that the species is the same." Here then we have another instance of a tropical plant being found in both hemispheres. How did it get there?

According to the present conformation of the land in tropical and sub-tropical seas, there is no water-passage open in those latitudes between the Atlantic and Pacific, or between the Atlantic and Indian Oceans. In the north and also in the south, round "the Horn," the extreme cold would be fatal to all the species of Sargassum; and although certain species of this genus grow at the Cape of Good Hope, *S. bacciferum* has never yet been brought home from thence.[6] The presence of the plant in the warmer parts of the three great oceans where means of communication are now impossible, except between the Indian and Pacific Oceans, owing to the conformation of the land and climatal obstructions, remains still to be accounted for. This can only be done by referring to a time when Mexico was submerged, and the isthmus not yet in existence, and there was thus communication between the tropical Atlantic and Pacific; when open passages also existed between the Indian Ocean and the warmer parts of the Atlantic, and between the Indian and Pacific Oceans. Tropical and sub-tropical algæ would thus be free to pass from sea to sea. That these plants did so is the opinion of botanists and other scientific persons. In support of this opinion may be mentioned the occurrence of a considerable

1 "Manual of British Marine Algæ," second edition.

2 The floating gulf-weed is not the only plant which can maintain life in vigour, and propagate itself without producing fruit. *Gigartina Teedii*, and *Griffithsia secundiflora*, have vegetated many years on rocks in the vicinity of Plymouth, without producing fruit. They are both natives of the Mediterranean, where they yield fruit freely.

6 Agardh, *l. c.*

number of sea-fishes inhabiting both sides of the Isthmus, which Dr. Günther has shown to be absolutely identical. To these may be added several species of mollusca. With reference to the mollusca Mr. Wallace[1] observes, "The long-continued separation of North and South America by one or more arms of the sea . . . is further rendered necessary by the molluscan fauna of the Pacific shores of tropical America, which is much more closely allied to that of the Caribbean sea, and even of West Africa, than to that of the Pacific Islands. The families of many of the genera are the same, and a certain proportion of very closely allied or identical species, shows that the union of the two oceans continued late into tertiary times. If fishes and mollusca could thus pass from ocean to ocean, there is no doubt that algæ could also pass. Besides *Sarg. bacciferum*, *S. vulgare*, and *S. dentifolium*, the following species, among others, are common to both hemispheres, namely, *Chnoospora fastigiata*, *Hydroclathrus cancellatus*, *Digenia simplex*, *Acanthophora Thierri*, and others too numerous to mention. It is further thought that such plants are among the oldest forms of algæ, and that algæ are among the oldest productions of the vegetable world. Geologists are of opinion that the tropical passage between the Atlantic and Pacific was open during the tertiary and cretaceous epochs. How long a time has elapsed since this period is another question that remains to be answered. This can only be done approximately. "From the Devonian period, or earlier," says Prof. Huxley,[2] "to the present day, the four great oceans, Atlantic, Pacific, Indian, and Antarctic, may have occupied their present positions, and only the coasts and channels of communication have undergone an incessant alteration." Mr. Croll, who, in his most interesting work "Climate and Time," brings astronomical science to bear upon the elucidation of geological problems, states that "the great ocean basins are probably of immense antiquity; that the great depressions of the Atlantic, Pacific, and Indian Oceans may be as old as the Laurentian period for any thing which geology shows to the contrary." He also remarks—"all our main continents and islands not only existed during the glacial period as they do now; the very contour of the surface was much the same as at the present day."[3] The migration of *S. bacciferum* from one ocean to the other must then have taken place previously to the commencement of the glacial period—the most recent glacial period, I mean—for Mr. Croll thinks that there were other glacial periods with intermediate warm periods during the tertiary epoch. He gives astronomical reasons[4] for saying that the commencement of the most recent glacial epoch cannot date back more than 240,000 years. As, then, there has been no material alteration of the surface of the land since that period, and our plant now inhabits and can live in the warmer parts only of the three great oceans, the barriers to their intercommunication being now closed as before-mentioned, it follows that this alga must be at least of greater antiquity than the glacial period, 240,000 years ago. How many thousands or hundreds of thousands additional years may be added to its age, it is impossible to say. Perhaps on some slab of rock from the depths of the earth the astonished and admiring botanist may yet recognise a fossil plant of the wandering Sargassum.[5]

If the presence of a great number of species in a limited area is suggestive that the parent-stock may have originated in that locality, then it is probable that the primary habitat of the genus Sargassum may have been in the Indian and adjacent oceans, since it is on the southern coasts of Asia, the islands in the Indian Ocean, and round the coasts of Australia and New Zealand (Mr. Wallace's "Oriental and Australian Regions," also his "Ethiopian Regions," Nos. 1 and 4), that the greater number of species of Sargassum are found. No less than forty species are known to inhabit the seas around Australia and New Zealand.

There are fair grounds for the opinion that many of the tropical algæ of the three great oceans are probably among the oldest forms of this class of plants—*S. bacciferum* and its congener *S. vulgare*, also *S. dentifolium*, and other algæ before mentioned may, therefore, be "survivals," still existing in health and vigour, of the marine vegetation of a very remote period, as ancient, at least, as the miocene[6] epoch, when the appearance and configuration of the country was, in all probability, different from what it is at the present day.

One cannot but look with wonder and admiration mixed with somewhat of veneration, on the wandering Sargussum, still in vigorous existence, which has survived so many changes of climate affecting different parts of the earth's surface; so much variation in the boundaries of the sea-shores; before which the rise and fall of empires, and the very existence of man, form almost inappreciable items in its life-history.

In order to show the great numerical increase in the species of Sargassum in the warmer seas, I shall conclude this article with a tabular view of their geographical distribution. In the division of regions I have followed Mr. Wallace. It is to be observed that as some species range through more than one region, they are consequently entered in each region, and thus the aggregate of species appears to be greater than it really is.

MARY P. MERRIFIELD

UNIVERSITY AND EDUCATIONAL INTELLIGENCE

THE Master of Trinity College, Cambridge, has forwarded to the Vice-Chancellor certain statutes made by the College affecting the University, and in doing so intimates that the Colleges consider that the provisions of the Universities of Oxford and Cambridge Act, 1877, do not bind them to postpone their final adoption until one month after they have been communicated to the Council of the Senate. The statutes have reference to, among others, the Trinity Professorship of Physiology. They provide that any person hereafter elected to the Professorship shall be entitled to a Fellowship at Trinity unless he is Master or Fellow of some other College. The Trinity Professor of Physiology is to receive an annual stipend of 500*l*., in addition to the emoluments of a Fellowship. The new statutes also provide that there shall be paid by the College to the University an annual sum calculated upon the amount of the distributable income of the College, which is particularly defined. Such annual sums to commence from the time the statutes come into operation, and shall be in the first instance equal to 5 per cent. of the distributable income, to be increased to 7½ per cent. when the statutes have been ten years in operation, and to 10 per cent. when they have been fifteen years in operation. The provisions of these statutes with respect to the Trinity Professorship of Physiology shall take effect from and after the appointment of the first Trinity Professor of Physiology, under the provisions of a statute or statutes to be made with the consent of the College for the establishment of the said professorship.

THE French Government proposes to do an act of justice in raising the stipends of professors in science and medicine to the same amount as in the case of law and letters, 15,000 francs. Dr. Simplice, who writes on the subject in the *Union Médicale*, points out how unequally professors of pure science, as botany and chemistry, are rewarded as compared with, say, clinical professors, who can add enormously to their income by private

[1] "Geographical Distribution of Animals," vol. ii., p. 58.

[2] Address to the Geological Society, reported in the *Journal* of the Geological Society, May, 1870.

[3] "Climate and Time," p. 9.

[4] *l.c.*, p. 355.

[5] Among the fossil algæ known to botanists are some specimens of Sargassum.

[6] Mr. J. S. Gardner, F.G.S., has recently expressed his opinion that the American continents became united during the eocene period (see NATURE, vol. xviii. p. 192). If this be the fact, a great addition must be made to the antiquity of these plants.

practice. Dr. Simplice proposes that a maximum salary should be given to the former, and a minimum to the latter. This is a subject that calls for consideration here as well as in France.

SOCIETIES AND ACADEMIES

Boston, U.S.A.

American Academy of Arts and Sciences, October 9.—Charles Francis Adams, president, in the chair.—Prof. W. A. Rogers read a paper on the limits of accuracy in measurements with the microscope, in which he stated that Prof. E. N. Morley and himself independently measured 195 spaces having a magnitude of about $\frac{1}{500}$ of an inch, each space, however, varying slightly from this value. The measures were made with a glass eye-piece micrometer, a Beck's spider line micrometer, and with a screw attached to the sub-stage of the microscope. After the results were prepared for the press they were for the first time compared. It was found that the average difference between the results for a single space was 32 millionths of an inch, and the greatest difference was 12 millionths. There were only four cases in which the difference amounted to one hundred thousandth of an inch.—In a second paper Prof. Rogers gave a determination of the errors of the sub-divisions of a copy of the British yard known as Bronze No. 11 and of the metre of the U.S. Bureau of Weights and Measures and the production therefrom of an inch, which is one thirty-sixth of this particular yard, and of a centimetre, which is one-hundredth part of this particular metre, the temperature in both cases being 67° F.—Prof. John Trowbridge described a new electro-dynamometer for measuring strong electric currents without shunting them. The principle consists in cooling the two points in the revolving axis of the instrument where the current enters and leaves by means of a current of water and in using mercury pivots. The instrument can measure from a fraction of a Weber up to six hundred Webers. It is especially adapted for the measurement of currents produced by dynamo-electric machines.

Göttingen

Royal Academy of Sciences, July 6.—The following papers were read:—On the solution of equations of the fifth degree, by L. Kiepert.—On *Duboisia myoporoides*, by W. Marmé.—Herr Hänselmann of Brunswick presented to the Academy the certified copies of eighty-two letters written by or addressed to Gauss.

August 3.—On the feldspar in the basalt of the Hohe Hagne, near Göttingen, and its relation to the feldspar from the Monte Gibele on the Island of Pantellaria.

Paris

Academy of Sciences, October 22.—M. Daubree in the chair.—The President announced the deaths of M. Bienaymé, free Academician, and M. Leymerie, correspondent in mineralogy.—M. Des Cloizeaux read a note on the works of the late M. Delafosse.—The following papers were read:—On the thermal formation of the combinations of oxide of carbon with other elements, by M. Berthelot. The heats liberated by chlorinised and sulphurised combinations of carbonic oxide are less than those of hydrogen: which corresponds to their less stability.—Various thermal determinations, by M. Berthelot. This relates to boric acid, chromate of soda, biacetate of soda, iodide of silicium, and earthy phosphates.—On the vision of colours, and especially on the influence exercised on vision of coloured objects in circular motion when observed comparatively with similar bodies in repose; extract from a small work by M. Chevreul. He supports the view of dyers and artists that there are three simple colours, viz., red, yellow, and blue. He finds, also, that by a motion having a maximum of 160 to 120 turns, and a minimum of sixty per minute, one may generate the complementary of every colour submitted to this movement.—On ytterbine, a new earth contained in gadolinite, by M. Marignac. The name is given to recall its presence in the mineral of Ytterby, also its similarity to yttria, on one hand, by absence of colour, and to erbine, on the other, by the elevation of its equivalent (say 131); to both, by the *ensemble* of its properties. The atomic weight deduced for ytterbium would be 115 or 172·5, according as its oxide receives the formula YbO or Yb_2O_3.—On the dentition of Smilodons, by M. Gervais.—The disease of chestnuts in the Cevennes, by M. Planchon. The gradual death of the stem and branches is caused by an alteration of the roots, which become softened with a sort of moist gangrene, giving out an exudation of tannic nature. These phenomena are caused by the mycelium of a fungus. M. Planchon thinks untimely irrigations are the chief *occasional* cause of the evil.—Processes for determining the butter in milk; reply to note by M. Adam, by M. Marchand.—Complementary observations on formulæ relating to perforation of iron armour plates, by M. Martin de Brettes.—M. Ponti, of Milan, announced his intention to place 60,000 Italian pounds at the disposal of the Academy, for founding an annual prize.—Observations on a communication from M. Amigues on flattening of the planet Mars, by M. Hennedy. He confirms M. Amigues' calculations from independent researches.—Remarks on M. Levy's note regarding a universal law relative to dilatation of bodies, by M. Boltzmann. He finds in fluid water a contradiction of M. Levy's theorem (about the pressure of an inclosed heated body increasing rigorously with the temperature).—Note relative to the theorem on the composition of accelerations of any order, by M. Lignine.—On the rectification of the ovals of Descartes, by M. Darboux.—Second note on the resolution in whole numbers of the equation (1) $ax^4 + by^4 = cz^2$, by M. Desboves.—On the Mosandrum of Prof. L. Smith, by M. Delafontaine. He rejects Prof. Smith's claim of priority, and affirms the identity of mosandric acid and terbine.—Researches on sulphates, by M. Etard. This relates to rose ferroso-ferric sulphates, mixed proto-sulphates, and simple or double sulphates, more or less hydrated.—On the nerve terminations in striated muscle, by M. Tschiriew. He has found, in several species, new forms of nerve-termination, intermediate between the motor termination (as met with in the frog), and the terminal plates. The most simple is in the tortoise; nerve-fibres deprived of myeline, ramify without anastomosing, and terminate, on the muscular bundles, by rods, sometimes smooth, but oftener moniliform, or surrounded by grains. There are generally several such terminations on one muscular fibre.—On the albuminoid matters of organs and of the spleen in particular, by M. Picard. Globuline exists in the spleen independently of the presence of blood.—On the hydrophorous reservoirs of Dypsacus, by M. Barthelemy. He rejects M. Boyer's view that the water present is produced by secretion (principally) and by dew, and attributes the liquid entirely to rain.—Apparatus for experimenting on the action of electricity on living plants, by M. Celi. This consists of a bell-jar, into which electricity is admitted by a metallic collector, connected with an insulated metallic vessel at 2 m. height, from which streams a thin vein of water.—Influence of salicylic and thymic acid, and some essences on germination, by M. Haeckel. While phenic acid suspends germination, salicylic acid (even in very small quantity) stops it altogether.
